Association Between More Intensive vs Less Intensive Blood Pressure Lowering and Risk of Mortality in Chronic Kidney Disease Stages 3 to 5
A Systematic Review and Meta-analysis

Cheung, MD; Girish N. Nadkarni, MD; Ruth L. Coleman, MSc; Rury R. Holman, MD; Alberto Zanchetti, MD; Ruth Peters, PhD; Nigel Beckett, MD; Jan A. Staessen, MD, PhD; Joachim H. Ix, MD, MAS

IMPORTANCE Trials in patients with hypertension have demonstrated that intensive blood pressure (BP) lowering reduces the risk of cardiovascular disease and all-cause mortality but may increase the risk of chronic kidney disease (CKD) incidence and progression. Whether intensive BP lowering is associated with a mortality benefit in patients with prevalent CKD remains unknown.

OBJECTIVES To conduct a systematic review and meta-analysis of randomized clinical trials (RCTs) to investigate if more intensive compared with less intensive BP control is associated with reduced mortality risk in persons with CKD stages 3 to 5.

DATA SOURCES Ovid MEDLINE, Cochrane Library, EMBASE, PubMed, Science Citation Index, Google Scholar, and clinicaltrials.gov electronic databases.

STUDY SELECTION All RCTs were included that compared 2 defined BP targets (either active BP treatment vs placebo or no treatment, or intensive vs less intensive BP control) and enrolled adults (≥18 years) with CKD stages 3 to 5 (estimated glomerular filtration rate <60 mL/min/1.73 m²) exclusively or that included a CKD subgroup between January 1, 1950, and June 1, 2016.

DATA EXTRACTION AND SYNTHESIS Two of us independently evaluated study quality and extracted characteristics and mortality events among persons with CKD within the intervention phase for each trial. When outcomes within the CKD group had not previously been published, trial investigators were contacted to request data within the CKD subset of their original trials.

MAIN OUTCOME AND MEASURE All-cause mortality during the active treatment phase of each trial.

RESULTS This study identified 30 RCTs that potentially met the inclusion criteria. The CKD subset mortality data were extracted in 18 trials, among which there were 1293 deaths in 15,924 participants with CKD. The mean (SD) baseline systolic BP (SBP) was 148 (16) mm Hg in both the more intensive and less intensive arms. The mean SBP dropped by 16 mm Hg to 132 mm Hg in the more intensive arm and by 8 mm Hg to 140 mm Hg in the less intensive arm. More intensive vs less intensive BP control resulted in 14.0% lower risk of all-cause mortality (odds ratio, 0.86; 95% CI, 0.76-0.97; \( P = .01 \)), a finding that was without significant heterogeneity and appeared consistent across multiple subgroups.

CONCLUSIONS AND RELEVANCE Randomization to more intensive BP control is associated with lower mortality risk among trial participants with hypertension and CKD. Further studies are required to define absolute BP targets for maximal benefit and minimal harm.
Chronic kidney disease (CKD) is a major public health problem, estimated to affect 26 million Americans and 200 million individuals worldwide.\textsuperscript{1,2} Persons with CKD are at high risk of cardiovascular disease (CVD), progression to end-stage renal disease (ESRD), and all-cause mortality.\textsuperscript{3} Hypertension is a well-known risk factor for CVD; therefore, optimal blood pressure (BP) control is a major clinical and public health priority.\textsuperscript{4,5} Over the past decade, several studies and clinical practice guidelines\textsuperscript{6-10} have addressed the optimal BP target in CKD populations, yet consensus remains elusive. Observational data have demonstrated U-shaped relationships between BP and mortality risk among those with CKD.\textsuperscript{11,12} Clinical trials testing different BP targets in CKD populations, including the Modification of Diet in Renal Disease (MDRD)\textsuperscript{13} and the African American Study of Kidney Disease and Hypertension (AASK),\textsuperscript{14} failed to demonstrate benefits of BP lowering for slowing down CKD progression and were underpowered to address CVD and mortality.

The current Kidney Disease: Improving Global Outcomes (KDIGO)\textsuperscript{7} BP guidelines recommend a BP goal less than 130/80 mm Hg for individuals with CKD and moderate to severe albuminuria and less than 140/90 mm Hg for those with CKD and albuminuria less than 30 mg/g. The Eighth Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 8)\textsuperscript{15} and the 2013 European Society of Hypertension/European Society of Cardiology Task Force\textsuperscript{16} affirmed the BP target of less than 140/90 mm Hg for individuals with CKD and made no distinction based on the albuminuria level. These guidelines were published before the Systolic Blood Pressure Intervention Trial (SPRINT)\textsuperscript{17} was completed. SPRINT enrolled hypertensive individuals without diabetes and with high CVD risk and found a substantially lower CVD risk and lower all-cause mortality risk in participants treated to a systolic BP (SBP) target less than 120 mm Hg compared with less than 140 mm Hg, although they found a significant excess of acute kidney injury (AKI). Patients with CKD (defined as an estimated glomerular filtration rate \textit{eGFR} of 20-59 mL/min/1.73 m\textsuperscript{2}) accounted for approximately 30% of the SPRINT participants, and the results were similar (no statistically significant interactions) among those with CKD compared with their non-CKD counterparts. However, the trial was not specifically powered to define the risks and benefits of intensive BP control for those with CKD.

The different definitions and differential reporting of AKI, CKD progression, and CVD events from previous randomized clinical trials (RCTs) represent a major challenge to comprehensively address these end points in a meta-analysis. In contrast, mortality is similarly defined across studies and is virtually always reported because it is an important safety signal. Mortality also provides a summary estimate of the net benefits and harms of the intervention. Therefore, our objective was to conduct a systematic review and meta-analysis of RCTs to investigate if more intensive compared with less intensive BP control is associated with reduced mortality risk in persons with CKD stages 3 to 5.

**Key Points**

**Question** Does intensive blood pressure lowering decrease the risk of mortality in patients with chronic kidney disease?

**Findings** In this meta-analysis of 18 randomized clinical trials comprising 15,924 patients with chronic kidney disease, more intensive blood pressure lowering was associated with significantly lower risk of mortality compared with less intensive blood pressure control.

**Meaning** Targeting more intensive blood pressure lowering may provide a mortality benefit in persons with chronic kidney disease.

**Methods**

**Electronic Searches** Ovid MEDLINE, Cochrane Library, EMBASE, PubMed, Science Citation Index, Google Scholar, and clinicaltrials.gov electronic database searches were completed from January 1, 1950, to June 1, 2016, with the following keywords: \textit{randomized controlled trials, intensive blood pressure treatment, intensive blood pressure control, strict blood pressure treatment, strict blood pressure control, tight blood pressure treatment, or tight blood pressure control}.\textsuperscript{18} The clinicaltrials.gov website was searched for randomized trials that were registered as completed but not yet published. The reference articles from each identified trial were reviewed to identify any additional relevant studies. No language restrictions were applied. The literature search was performed according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA)\textsuperscript{19} statement recommendations (eTable 1 in the Supplement).

**Selection of Studies** Study eligibility was individually determined independently by 2 of us (R.M. and H.A.N.). Eligible for inclusion were both open-label and double-blinded RCTs that had adult participants (≥18 years) with CKD stages 3 to 5, which was defined as an \textit{eGFR} less than 60 mL/min/1.73 m\textsuperscript{2} by either the MDRD or Chronic Kidney Disease Epidemiology Collaboration equations and had randomized participants to 2 defined BP targets (either active BP treatment vs placebo or no treatment, or more intensive vs less intensive BP control). In some instances, identified trials included persons with CKD, but the trials had not previously published mortality events within the CKD subset. In such cases, we contacted the study investigators and requested data on the number of patients with CKD enrolled in the trial, the number in each treatment arm, and the number of deaths that occurred during the active trial phase. Studies among dialysis patients were excluded.

**Data Extraction and Quality Assessment** Demographics, comorbid characteristics, enrollment criteria, BP control targets in each arm, mean reductions in SBP and diastolic BP, and mortality events were extracted onto standardized extraction forms. Extracted data were then verified by another one of us (H.A.N.). For any discrepancies, two of us (R.M. and H.A.N.) met and conferred, and consensus was
The primary outcome was all-cause mortality. The mortality data were obtained during the active treatment phase of each trial. The mortality events that occurred during extended follow-up after the active phase of each trial were not included.

Outcome Measures
The quality and clinical generalizability of each study were assessed according to the methods based on allocation concealment, masking (of participants, investigators, and assessor), intent-to-treat analysis, percentage withdrawals, and whether withdrawals were adequately described. 20

Statistical Analysis
Mortality outcomes in each randomized BP group were pooled, and weighted odds ratios (ORs) comparing the lower BP arm (intensive BP) with individuals randomized to higher BP targets (less intensive or placebo) and their 95% CIs were calculated using both random-effects and fixed-effects models. The influence of individual trials on the pooled effect size was assessed, and a trial was considered to have an excessive influence if, after its exclusion, the point estimate of the remaining trials was outside the 95% CI of the overall risk estimate. Heterogeneity was assessed based on I² test (I² of 0%-25% indicates no or mild heterogeneity, 25%-50% indicates moderate heterogeneity, 50%-75% indicates large heterogeneity, and 75%-100% indicates extreme heterogeneity). 20 Subgroup analyses were performed stratified by type of study (drug vs placebo vs 2 defined BP target arms), study trial duration, inclusion of diabetic patients (yes or no), baseline SBP, level of achieved SBP during the trial phase, and SBP difference between the 2 randomized arms. Meta-regression analysis was performed to assess the association between SBP differences during the trial phase and mortality risk while adjusting for baseline SBP. Potential publication bias was assessed using funnel plots. Two-sided P < .05 was considered statistically significant for all analyses, including tests for heterogeneity. All statistical analyses were performed using a software program (Comprehensive Meta-Analysis, version 2.2.064; Biostat Inc).

Results

Literature Search
The initial search of Ovid MEDLINE, Cochrane Library, EMBASE, PubMed, Science Citation Index, Google Scholar, and clinicaltrials.gov electronic databases between January 1, 1950, and June 1, 2016, provided 4416 citations. We reviewed abstracts and limited this search to a more detailed review of 407 abstracts of studies potentially eligible for inclusion as described in the Methods section. In subsequent review, 377 studies were excluded because they did not fulfill the inclusion criteria. The remaining 30 studies were reviewed in full text and identified for meta-analysis (Figure 1). Data elements from 9 trials 31,14,17,21-27 were extracted from the publications. One citation is a previous meta-analysis, 21 which was also used to abstract data. We contacted trial investigators for the remaining trials, and the authors of 9 studies 28-36 provided data on the number of participants with CKD and deaths during the trial phase for the 2 BP arms for the purpose of inclusion in this meta-analysis. We were unable to obtain mortality data in the CKD subset from the investigators for the remaining 12 trials. 37-48 Therefore, 18 RCTs involving 15,924 participants with CKD and complete data were included in the meta-analysis (Figure 1).

Study Characteristics
eTable 1 in the Supplement summarizes the main characteristics of the studies included in the meta-analysis. All trials were of good quality. Each used a parallel treatment group design, and 15 trials reported adequate methods for random allocation and concealment of treatment assignment (eTable 2 in the Supplement). Six trials 13,14,22-26,28-35 had excluded patients with type 1 diabetes, whereas 3 trials 14,17,23 had excluded patients with all forms of diabetes. Thirteen trials 13,14,17,22,25,31-36 among the 18 had 2 defined BP targets, and the remaining 5 trials 26-30 evaluated a BP-lowering intervention vs no treatment or a placebo arm. One trial 36 had 3 defined BP targets. For the purpose of this meta-analysis, the lowest BP target group was compared with the other 2 groups together. The BP targets varied across trials (eTable 1 in the Supplement). The mean (SD) baseline SBP was 148 (16) mm Hg in both the intensive and less intensive arms. The mean SBP decreased by 16 mm Hg to 132 mm Hg in the more intensive arms and by 8 mm Hg to 140 mm Hg in the less intensive arms. The median follow-up period was 3.6 years (interquartile range [IQR], 2.8-4.9 years). The median difference in SBP achieved across arms 13,14,17,22,25-36 was 10 mm Hg (IQR, 4-12 mm Hg), with a median of 130 mm Hg (IQR, 125-141 mm Hg) in the more intensive arms vs 138 mm Hg (IQR, 134-146 mm Hg) in the less intensive arms. The renal inclusion and exclusion criteria varied across trials and are summarized in eTable 1 in the Supplement.
Blood Pressure Lowering and Risk of Mortality in Chronic Kidney Disease

Figure 2. Effect of Intensive Blood Pressure (BP) Lowering on Risk of Mortality in Hypertensive Trial Participants With Chronic Kidney Disease

In the 18 included trials,\(^\text{13,14,17-22,26}\) there were 584 deaths among 7451 participants in the more intensive BP arm and 709 deaths among 8473 participants in the less intensive BP arm during the trial phase. The trial by Howard et al\(^\text{31}\) had no mortality outcomes in both BP arms (more intensive vs less intensive) and was dropped from the analysis.

BP Control and Risk of Mortality

Figure 2 shows the main results of the meta-analysis. In the 18 included trials, there were 584 deaths among 7451 participants (7.8%) in the more intensive BP arm and 709 deaths among 8473 participants (8.4%) in the less intensive BP arm during the trial phase. Using the random-effects model, the OR for death among participants with CKD randomized to the more intensive BP-lowering arm was 0.86 (95% CI, 0.76-0.97; P = .01) compared with the less intensive BP arm. The results were similar with the fixed-effects model. None of the individual trials had an excessive influence on the pooled effect size. There was no evidence of heterogeneity across studies (P = .0%); P for heterogeneity = .77). Funnel plot analysis revealed no evidence of publication bias based on visual inspection (Figure 3) or by performing Begg and Mazumdar rank correlation (P = .23) and Egger regression (P = .08) tests. Because we knew a priori that SPRINT had found that intensive BP control improved mortality and provided substantial statistical power to this meta-analysis, we specifically evaluated the remaining trials with the exclusion of SPRINT in a sensitivity analysis. The results were similar in this analysis (OR, 0.88; 95% CI, 0.78-0.99; P = .05).

Subgroup Analysis

The observed effect of those randomized to the more intensive BP arm on mortality was consistent irrespective of the following: type of treatment in the comparator arm (placebo or less intensive BP target), median follow-up duration (<3 vs ≥3 years), inclusion of diabetic patients (yes or no), CKD severity (serum creatinine level <2.0 mg/dL or creatinine clearance >30 mL/min/1.73 m\(^2\)) vs serum creatinine level ≥2.0 mg/dL or creatinine clearance ≤30 mL/min/1.73 m\(^2\)), baseline SBP of the entire cohort (<140 mm Hg vs 140-160 mm Hg vs >160 mm Hg), or achieved SBP in the more intensive lowering group (SBP<125 mm Hg vs SBP 125-135 mm Hg vs SBP >135 mm Hg) (Figure 4). (To convert creatinine level to micromoles per liter, multiply by 88.4; creatinine clearance to milliliters per second per meter squared, multiply by 0.0167.)

In the trials that achieved a difference in SBP of at least 12 mm Hg, the OR of death in the more intensive vs less intensive arms was 0.76, trials with differences exceeding 6 but less than 12 mm Hg had an OR of 0.97, and those with differences of 6 mm Hg or less had an OR of 1.06; formal testing for heterogeneity resulted in a P value of .06. Meta-regression adjusting for baseline SBP level showed a similar pattern suggesting greater mortality benefit in trials with higher differences in achieved BP across treatment arms, although this finding did not reach statistical significance (slope of log OR per mm Hg difference in SBP, −0.0201; 95% CI, −0.0499 to 0.0097; P = .19) (eFigure in the Supplement).

Discussion

In this systematic review and meta-analysis of 18 RCTs among 15 924 participants with both hypertension and an eGFR less than 60 mL/min/1.73 m\(^2\) randomized to more intensive vs less intensive BP lowering, those randomized to more intensive BP lowering had 14.0% lower risk of all-cause mortality. We observed a suggestion of a mortality benefit in studies that achieved the greatest difference in SBP between the 2
The findings of this meta-analysis may have implications to both clinical practice and public health policy. Relative to public policy, the KDIGO Blood Pressure Work Group\(^4\) announced that they have convened a panel of experts to review evidence and potentially modify their guideline recommendations regarding appropriate BP targets in patients with CKD. The present meta-analysis may provide useful data for the upcoming guideline review. Our results may also offer additional information for patients and health care professionals and may be useful to guide shared decision making about the relative risks and benefits of BP lowering among those with CKD.

**Strengths and Limitations**

This study has several strengths. First, multiple high-quality, methodologically rigorous randomized trials had not previously reported differences in death rates across treatment arms in persons with prevalent CKD. Among the 18 trials included in this meta-analysis, investigators from 9 trials reevaluated their data within the CKD subset and provided data specifically to support this study. Therefore, our meta-analysis provides a substantial new evidence base about the risks and benefits of intensive BP lowering in populations with CKD. Second, we assessed mortality as a hard clinical

---

**Figure 3. Studies Evaluating Intensive Blood Pressure Control Relative to Mortality Among Persons With Chronic Kidney Disease**

A symmetrical inverted funnel implies no publication bias. Each open circle represents an individual published study.
outcome, which has obvious clinical importance, is similarly ascertained across studies, and is thus largely free of bias. Third, we restricted our analysis to outcomes that were assessed during the trial phase of each study only and excluded events that occurred during long-term follow-up. While there is important information obtained in such follow-up,55 BP control often approached similar levels across treatment arms after the trial phase. Although additional studies and intensive monitoring for safety are warranted, these do not provide an estimate of an optimal BP target in patients with CKD. We recognize that CVD events, CKD progression, AKI, and ESRD are important factors that may be in the causal pathway between more intensive BP lowering and mortality and were not able to assess these end points.

Our study also has important limitations. First, despite considerable efforts to contact investigators, we were not able to obtain data on mortality in persons with CKD in several prior clinical trials. Therefore, these trials were excluded by necessity. Among the 18 studies with almost 16 000 participants with CKD, we found no evidence of heterogeneity. This observation provides confidence, although not certainty, that the results would likely have been similar with the inclusion of additional studies. Second, we lacked data by severity of CKD and thus could not evaluate the effect of more intensive BP lowering on mortality stratified by CKD severity. Most individuals in the included trials had CKD stage 3, and we acknowledge that the risks and benefits of more intensive BP lowering may differ in persons with more advanced CKD. Third, baseline BP and the intensity of BP reduction in the randomized treatment arms differed across the individual trials. As such, we are not able to provide an estimate of an optimal BP target in patients with CKD. We recognize that CVD events, CKD progression, AKI, and ESRD are important factors that may be in the causal pathway between more intensive BP lowering and mortality and were not able to assess these end points.

Conclusions

Among trial participants with hypertension and an eGFR less than 60 mL/min/1.73 m², randomization to more intensive BP lowering was associated with lower risk of all-cause mortality. This finding was consistent across trials, with no evidence of heterogeneity. A nonsignificant suggestion of greater mortality benefit was observed in trials that achieved the greatest difference in SBP across arms. Although additional studies and intensive monitoring for safety are warranted, these data support that the net benefits may outweigh the net harms of more intensive BP lowering in persons with CKD.
