A Double-blind, Placebo-Controlled, Crossover Study of Sildenafil in Obstructive Sleep Apnea

Suely Roizenblatt, MD, PhD; Christian Guilleminault, MD, BiolD; Dalva Poyares, MD, PhD; Fatima Cintra, MD, PhD; Adriana Kauati, PhD; Sergio Tufik, MD, PhD

Background: Sildenafil prolongs the action of cyclic guanosine monophosphate and nitric oxide by inhibiting cyclic guanosine monophosphate–specific phosphodiesterase 5. It is largely used for erectile dysfunction, a highly prevalent condition in obstructive sleep apnea. Because nitric oxide promotes upper airway congestion, muscle relaxation, and pulmonary vasodilation, the aim of this study was to establish the impact of a single 50-mg dose of sildenafil on the sleep of patients with severe obstructive sleep apnea.

Methods: Fourteen middle-aged men with severe obstructive sleep apnea were consecutively selected for this double-blind, placebo-controlled, crossover study. Exclusion criteria were obesity, cardiovascular and/or respiratory disease, and conditions that interfere with sleep. All-night polysomnography was preceded by a single 50-mg dose of sildenafil or matching placebo randomly administered at bedtime, after a washout period of 1 week.

Results: In comparison to placebo, a single 50-mg dose of sildenafil significantly increased the percentage of total sleep time with an arterial oxygen saturation of less than 90% (mean±SD, 14.2%±9.1% vs 8.5%±3.2%, P<.01), without a difference in the nadir of oxygen desaturation. The mean arterial oxygen saturation also decreased (92.1%±1.91% vs 93.8%±1.3%, P=.02), and the desaturation index increased (30.3±18.1 events per hour vs 18.5±14.6 events per hour, P<.001). There was an increase in apnea-hypopnea index (42.4±25.5 events per hour vs 34.6±24.1 events per hour, P=.01), involving mostly obstructive events.

Conclusion: In patients with severe obstructive sleep apnea, a single 50-mg dose of sildenafil at bedtime worsens respiratory and desaturation events.

Arch Intern Med. 2006;166:1763-1767

Sildenafil is a potent and selective inhibitor of cyclic guanosine monophosphate–specific phosphodiesterase 5. Therefore, it prolongs the action of cyclic guanosine monophosphate, the second messenger of nitric oxide (NO), resulting in augmented smooth muscle relaxation and vasodilation. Phosphodiesterase 5 is expressed in many tissues other than the sinusoids of the corpus cavernosum of the penis. Among the structures that may play a role in the pathogenesis of obstructive sleep apnea (OSA), phosphodiesterase 5 is expressed in nasal mucosa, tracheobronchial muscles, and pulmonary vasculature. By increasing the availability of NO, sildenafil could potentially impair respiratory function by interfering with nasal patency and by promoting relaxation of the pharyngeal muscles. Because of the vasodilatory effect of NO on the pulmonary arterial bed, an increase in the right-to-left shunt volume has been described by some authors, but not by others, in healthy individuals.

A growing body of evidence suggests that OSA is a major contributing factor in the development of erectile dysfunction; however, erectile dysfunction remains undiagnosed in 80% of patients with OSA, even in cases in which there are clear signs and symptoms of the condition. Using a double-blind, placebo-controlled, crossover design, we assessed the effects of a single 50-mg oral dose of sildenafil at bedtime on the results of polysomnography in patients with severe OSA without pulmonary hypertension.

METHODS

STUDY PARTICIPANTS

Forty-nine middle-aged men with severe OSA who were consecutively selected from the database of the Sleep Laboratory of the Federal University of São Paulo, São Paulo, Brazil, were recruited for participation in our study. The inclusion criteria were age between 40 and 65 years, a body mass index (weight in kilograms divided by the height in meters squared)
of less than 30, an apnea-hypopnea index (AHI) of more than 30 events per hour of total sleep time (TST), and an oxygen desaturation (≥4%) index of 10 or more, as evidenced by recent polysomnography (performed <6 months earlier). Criteria of exclusion were daytime hypoxemia, concomitant significant debilitating illness, use of nitrates or drugs that could influence sleep, current alcohol or drug abuse, and current or previous history of smoking more than 10 cigarettes a day. Further exclusion criteria were acute or chronic respiratory disease based on symptoms and respiratory function test results, systemic arterial hypertension, and evidence of previous or present cardiac disease based on symptoms, 12-lead electrocardiography, or Doppler echocardiography. Subjects who participated in trials with continuous positive airway pressure therapy inclusion criteria also had an awake apnea-hypopnea index (AHI) of 10 or more. Exclusion criteria were acute or chronic respiratory diseases, electrocardiography, Doppler echocardiography, or other respiratory disease, or presence of vascular or metabolic disease (ie, arterial hypertension, coronary artery disease, cerebrovascular disease, hypercholesterolemia, and diabetes mellitus) and smoking habits. Test patients and the investigator were blinded to the patients’ sleep-history. Three polysomnograms of each subject according to the parameters of the task force of the American Sleep Disorders Association were reviewed.17

STUDY DESIGN

All participants, after signing informed consent, were evaluated for the presence of vascular or metabolic disease, obesity, coronary artery disease, cerebrovascular disease, hypercholesterolemia, and diabetes mellitus. To exclude cardiac and pulmonary hypertension (defined as pulmonary arterial pressure ≥20 mm Hg) and other respiratory diseases, electrocardiography, Doppler echocardiography, and respiratory function tests were performed. Subjects with negative findings (14 of 49) were submitted to baseline nocturnal polysomnography. Subjects who participated in trials with continuous positive airway pressure therapy were selected (age 53.1±9.8 years; body mass index, 26.7±1.9). The most important effects of a single 50-mg dose of sildenafil at bedtime were a significant increase in desaturation index, a significant increase in the percentage of TST with an SaO2 of less than 90%, a significant increase in the maximal duration of a desaturation event, and a decrease in the mean SaO2, as well as an increase in the AHI, owing to an increase in obstructive events, and in the percentage of TST elapsed in a hypopnea (Table 1). There was no significant difference in the percentage of TST spent in the supine position among baseline, sildenafil, and placebo nights: (29.8±13.8%, 28.0%±12.0%, and 28.5%±12.1%, respectively).

Sleep structure was also modified by the use of sildenafil, with an increase in stage 2 of non–rapid eye movement (non-REM) sleep in comparison to placebo and a decrease in slow-wave sleep in comparison to baseline and placebo. These changes were seen even though no significant differences were observed among conditions in TST, sleep latency, REM latency (6.7±4.0 minutes vs 9.0±5.3 minutes [P=.10]) and 99.3±43.9 minutes vs 123.6±33.1 minutes [P=.20], respectively), and percentage of the other sleep stages (Table 2). The Figure shows the results of hypnography and oximetry in 4 subjects during placebo and sildenafil intake. Compared with those of placebo, the most common adverse effects of sildenafil were headache (2 patients vs 5 patients), flushing (1 patient vs 6 patients), and nasal congestion (2 patients vs 5 patients). Four patients reported more than 1 of these adverse effects.
To our knowledge, this double-blind, placebo-controlled, crossover study is the first to demonstrate that sildenafil, administered as a single 50-mg oral dose, can aggravate respiratory manifestations in middle-aged patients with severe OSA without pulmonary hypertension or other significant lung disease in terms of increase in obstructive respiratory events and in desaturation.

In order to evaluate the impact of sildenafil on patients with severe OSA, we were careful to eliminate subjects with conditions that could influence the analysis. A large number of the recruited patients were therefore excluded because of respiratory, cardiovascular, or metabolic syndrome diagnoses established previously or by our study’s screening test. Our study subjects had only severe OSA, and there may be subjects in the general population who use sildenafil and are unaware of their OSA.

Since the introduction of sildenafil in 1998,1 an increasing percentage of middle-aged men have used selective phosphodiesterase 5 inhibitor drugs to treat erectile dysfunction.19,20 Erectile dysfunction is frequent in persons with OSA, which is a condition that is related to middle-age11-14 and characterized by repetitive, complete, or partial upper airway occlusion. Hypoxemia can result from ventilation-perfusion mismatch, with a decrease in ventilation in normally perfused alveoli. Pulmonary vascular remodeling and hypoxic vasoconstriction, as a consequence of perfusion of unventilated alveolar units, is a compensatory mechanism to minimize regional ventilation-perfusion inequality during the episodic obstructions of airflow during sleep.22,23 Sildenafil increases the availability of NO, which may reverse the hypoxic vasoconstriction of the pulmonary circulation.24 It has been reported that in anesthetized, otherwise-normal pigs sildenafil administration augmented intrapulmonary shunt flow and lowered SaO2.6 However, in subjects who were exposed to high altitudes, the use of sildenafil caused a suppression of the hypoxia-induced increase in mean pulmonary artery pressure, which was associated with an increase in blood oxygenation.25 Similar findings were seen in patients with lung

fibrosis and secondary pulmonary hypertension in whom there was an improvement in pulmonary gas exchange that was probably related to selective pulmonary vasodilation in ventilated areas of the lungs. However, when nonselective vasodilators were used in patients with primary or secondary pulmonary hypertension, there was worsening of oxygenation as a result of blood flow to poorly ventilated or nonventilated areas of the lung, thereby worsening preexisting ventilation-perfusion mismatch and shunt flow.

The increase in time spent asleep with an \( \text{SaO}_2 \) of less than 90% was the major finding of this study. This increase in the severity of decreases in \( \text{SaO}_2 \) was associated not only with an increase in the frequency of obstructive apnea and hypopnea events but also with an increase in the duration of these events. These findings are consistent with the expression of undiagnosed respiratory events and may be a concern regarding the use of sildenafil by subjects with severe OSA.

It is well known that upper airway caliber is reduced during sleep and that air passage is further impaired by decreased activity of upper airway muscles, particularly the muscles involved with tonic activity (independent of the phase of respiration), such as the tensor veli palatini muscle. The mechanical consequence of reduced airway caliber is increased upper airway resistance. Because pharyngeal compliance increases during non-REM sleep, negative intrathoracic pressures normally produced in the upper airway during inspiration will result in airway collapse. Even in healthy individuals, negative intrathoracic pressure during non-REM sleep limits inspiratory flow, resulting in an inspiratory plateau that persists in the presence of increasing negative pressure.

The increase in the number and duration of apnea-hypopnea events may be related to the effect of sildenafil in prolonging the effect of NO in nasal mucosa, leading to congestion. This effect is important enough to be reported by 4% to 12% of users and may further in-

**Figure.** Results of polysomnography after administration of placebo and sildenafil in 4 patients with severe obstructive sleep apnea. After a single 50-mg dose of sildenafil is administered at bedtime, an increase in the frequency and intensification of the desaturation of oxyhemoglobin is seen. REM indicates rapid eye movement; sleep time, number of hours of sleep; and W, wake.
increase nasal resistance, decrease airway passage, and increase the frequency of airway collapse during sleep. In OSA, the accumulation of muscular NO may exacerbate muscle fatigue, and the inhibition of NO synthase, which lowers NO output, seems to protect against it. Sildenafil increases NO availability, consequently yielding to accumulation of reactive nitrogen and oxygen, which may increase the tendency of upper airway collapsibility. Even though sildenafil is rapidly absorbed, reaches maximal plasma concentration within 1 hour, and has a mean terminal half-life of 3 to 5 hours after oral administration, to our knowledge there are no available studies on the duration of sildenafil’s respiratory effects. The respiratory findings cannot be attributed to change in TST or in non-REM/REM distribution. The only difference among the baseline, placebo, and sildenafil conditions was the decrease in slow-wave sleep, which can be explained by the worsening of breathing during sleep. Although less likely, the decrease in slow-wave sleep may also have contributed to a change in the AHI.

It is interesting to note that the arousal index did not increase significantly, despite the increase in the AHI and SaO2 after the use of sildenafil, which can be attributed to the great variability of the data, particularly in the sildenafil group, as shown in Table 2. Since arousal can be considered as a defense mechanism in OSA, the lack of increase in arousals is consistent with the findings of longer respiratory events in this study. Our study cannot address the question of whether a possible sleep fragmentation at the beginning of the night, when the plasma peak of sildenafil occurs, is sufficient to blunt responses to obstruction at the end of the night. One of the study’s limitations is the lack of temporal analysis of the respiratory function during sleep. Another limitation is the limited sample size. Therefore, it is premature to extrapolate our findings to all individuals with sleep-related breathing disorder before properly designed randomized, controlled trials on the effects of sildenafil and other phosphodiesterase 5 inhibitors on pulmonary gas exchange and hemodynamics are performed in patients with different severity of sleep-related breathing disorder. Nevertheless, sildenafil should be used with caution for treatment of erectile dysfunction in individuals with a sleep-related breathing disorder. Finally, although we were not able to clarify the mechanisms responsible for the intriguing results of the present study, we found that the use of sildenafil interfered with the compensatory mechanisms in patients with OSA, increasing the frequency and duration of respiratory and desaturating events.

Correction

Errors in Abstract and Text. In the Original Investigation by Roizenblatt et al titled “A Double-blind, Placebo-Controlled, Crossover Study of Sildenafil in Obstructive Sleep Apnea,” published in the September 18 issue of the Archives (2006;166:1763-1767), errors appeared in both the abstract and the text. In the “Methods” section of the abstract, the first word should have been “Thirteen” because 13, rather than 14, participants were included in the study; therefore, the “Results” section of the abstract should have read, “In comparison to placebo, a single 50-mg dose of sildenafil significantly increased the percentage of total sleep time with an arterial oxygen saturation of less than 90% (mean ± SD, 15.6%±9.6% vs 7.9%±3.3%, P<.01), without a difference in the nadir of oxygen desaturation. The mean arterial oxygen saturation also decreased (92.1%±1.9% vs 93.8%±1.3%, P=.03), and the desaturation index increased (30.3±14.5 events per hour vs 18.5±9.1 events per hour, P<.001). There was an increase in apnea-hypopnea index (48.1±20.8 events per hour vs 32.3±11.3 events per hour, P<.001), involving mostly obstructive events.” Also, the first sentence of the “Results” section of the text on page 1764 should have read, “As mentioned, after screening for cardiovascular and pulmonary disease or metabolic syndrome, only 13 of the 49 middle-aged men with severe OSA recruited for this study were selected (age, 53.1±9.8 years; body mass index, 26.7±1.9).”
