Effect of Telephone-Administered vs Face-to-face Cognitive Behavioral Therapy on Adherence to Therapy and Depression Outcomes Among Primary Care Patients
A Randomized Trial

Depression is common, with the 1-year prevalence rate of major depressive disorder estimated at between 6.6% and 10.3% in the general population and roughly 25% of all primary care visits involving patients with clinically significant levels of depression. Psychotherapy is effective at treating depression, and most primary care patients prefer psychotherapy to antidepressant medications. When referred for psychotherapy, however, only a small percentage of patients follow through. Attrition from psychotherapy in randomized controlled trials is often 30% or greater and can exceed 50% in clinical practice.

The discrepancy between patients' preference for psychotherapy and the low rates of initiation and adherence is likely due to access barriers. Approximately 75% of depressed primary care patients report barriers that make it extremely difficult or impossible to attend regular psychotherapy sessions. These barriers are largely structural and include time constraints, lack of available and accessible services, transportation problems, and cost.

Context Primary care is the most common site for the treatment of depression. Most depressed patients prefer psychotherapy over antidepressant medications, but access barriers are believed to prevent engagement in and completion of treatment. The telephone has been investigated as a treatment delivery medium to overcome access barriers, but little is known about its efficacy compared with face-to-face treatment delivery.

Objective To examine whether telephone-administered cognitive behavioral therapy (T-CBT) reduces attrition and is not inferior to face-to-face CBT in treating depression among primary care patients.

Interventions Eighteen sessions of T-CBT or face-to-face CBT.

Main Outcome Measures The primary outcome was attrition (completion vs non-completion) at posttreatment (week 18). Secondary outcomes included masked interviewer-rated depression with the Hamilton Depression Rating Scale (Ham-D) and self-reported depression with the Patient Health Questionnaire-9 (PHQ-9).

Results Significantly fewer participants discontinued T-CBT (n=34; 20.9%) compared with face-to-face CBT (n=53; 32.7%; P=.02). Patients showed significant improvement in depression across both treatments (P < .001). There were no significant treatment differences at posttreatment between T-CBT and face-to-face CBT on the Ham-D (P = .22) or the PHQ-9 (P = .89). The intention-to-treat posttreatment effect size on the Ham-D was d=0.14 (90% CI, −0.05 to 0.33), and for the PHQ-9 it was d=−0.02 (90% CI, −0.20 to 0.17). Both results were within the inferiority margin of d=0.41, indicating that T-CBT was not inferior to face-to-face CBT. Although participants remained significantly less depressed at 6-month follow-up relative to baseline (P < .001), participants receiving face-to-face CBT remained less depressed relative to baseline; however, those receiving face-to-face CBT were significantly less depressed than those receiving T-CBT on the Ham-D (difference, 2.91; 95% CI, 1.20-4.63; P < .001) and the PHQ-9 (difference, 2.12; 95% CI, 0.68-3.56; P = .004).

Conclusions Among primary care patients with depression, providing CBT over the telephone compared with face-to-face resulted in lower attrition and close to equivalent improvement in depression at posttreatment. At 6-month follow-up, patients remained less depressed relative to baseline; however, those receiving face-to-face CBT were less depressed than those receiving T-CBT. These results indicate that T-CBT improves adherence compared with face-to-face delivery, but at the cost of some increased risk of poorer maintenance of gains after treatment cessation.

A meta-analysis of trials of telephone-administered psychotherapy found a mean attrition rate of 7.6%, suggesting that telephone delivery may reduce attrition. Telephone care has also been incorporated into aspects of collaborative care models that integrate mental health specialists into primary care settings. Although telephone-administered psychotherapy for depression has been tested as a tool to deliver care and overcome access barriers within primary care, the underlying assumptions that it is as effective as face-to-face care and that it reduces attrition have not been examined.

We describe a randomized trial comparing standard face-to-face cognitive behavioral therapy (CBT) vs a telephone-administered cognitive behavioral therapy (T-CBT) for the treatment of depression in primary care. It was hypothesized that T-CBT would produce lower levels of attrition and within primary care, the underlying assumptions that it is as effective as face-to-face care and that it reduces attrition have not been examined.

Randomization and Masking
An independent statistician used computer-generated randomized allocation with a 1:1 ratio, stratified by antidepressant status and therapist, with block size of 4 within each stratum. To prevent allocation bias, randomization was conducted after entry criteria were confirmed. Clinical evaluators, who were masked to treatment assignment, enrolled and evaluated participants; if they became unmasked, participants were reassigned to another masked evaluator.

Treatments
Face-to-face CBT and T-CBT used the same CBT protocol, with treatment delivery medium being the only factor that varied between conditions. This treatment model has been adapted and validated for telephone administration. Participants received 18 45-minute sessions: 2 sessions weekly for the first 2 weeks, followed by 12 weekly sessions, with 2 final booster sessions during 4 weeks. All participants received a patient workbook that included 8 chapters covering CBT concepts, including behavioral activation, cognitive restructuring, and social support, along with 5 optional modules that covered common comorbidities and treatment content, including anxiety and worry, relaxation training, communication and assertiveness training, anger management, and insomnia.

T-CBT telephone calls were initiated by the therapist. Nine therapists, all PhD-level psychologists, provided both face-to-face CBT and T-CBT to eliminate therapist effects. Face-to-face CBT was provided in the Preventive Medicine clinic at Northwestern University, located in the same medical center as the primary recruitment clinics. T-CBT was provided entirely over the telephone. Specific rules to ensure privacy and safety were discussed in the first session, such as being in a private place during telephone calls and not engaging in therapy while driving. Protocols were in place to ensure safety, which could include calling local emergency personnel to conduct a health and safety check in the event of severe suicidality.

All therapists received 2 days of initial training, followed by supervised training from the Beck Institute Director of Education (L.S.) until the therapists reached the competence criterion defined as consistent scores of greater than or equal to 40 on the Cognitive Therapy Scale, at which point they began treating study participants. Once trained, therapists received weekly supervision by the Beck Education Director or a Beck-certified psychologist for at least 6 months, which could then be reduced to once every 2 to 3 weeks, as determined by the supervisor. All sessions were audiotaped and 8% were rated on the Cognitive Therapy Scale for fidelity. Fidelity ratings were used in the supervision of the therapists.

This trial is focused on the treatment delivery medium. To prevent confounding through differences in the management of nonadherent patients across treatment arms, the therapist protocol included specific instructions for handling missed sessions and cancellations. A session was considered missed...
if less than 24 hours’ notice was given. If patients missed a session, they received 2 therapist telephone calls followed by a letter, after which, if still nonresponsive, the patients were determined to have discontinued treatment. Participants did not pay for treatment.

Outcome Assessment
The primary outcome was adherence to treatment, defined as attending therapy sessions. Participants were permitted to reschedule sessions if they notified their therapist 24 hours before a cancellation. The primary outcome was dichotomized as completion vs noncompletion of 18 sessions. Secondarily, we examined failure to engage in treatment (completion of ≤4 sessions), failure to complete (>4 sessions but <18 sessions), and number of sessions completed.

The secondary outcome, depression severity, was measured with the interviewer-rated 17-item Ham-D and the self-reported Patient Health Questionnaire—9 (PHQ-9). Psychiatric diagnoses, including major depressive disorder, were evaluated with the Mini International Neuropsychiatric Interview. Remission used the Ham-D abbreviated 7-item scale criterion, whereas the patients reported their treatment preference (face-to-face, telephone, or no preference). To identify any potential effects of systematic therapist expectation bias, the patients received no fewer than 16 hours of training on the Mini International Neuropsychiatric Interview and Ham-D, including receiving didactic instruction, role playing, and performing ratings on a library of existing taped interviews. All study interviews were audiotaped and were supervised by a psychologist until reliable proficiency was established. Supervision continued thereafter every 1 to 2 weeks. One audiotape was randomly selected every 1 to 2 weeks for calibration ratings to ensure interrater reliability. The mean interclass correlations were 0.96. All training and supervision were performed by a licensed PhD-level psychologist (J.H.).

Statistical Analysis
The study was designed to enroll 322 participants, resulting in 90% power for a 2-sided test at \( \alpha = .05 \) to detect a difference in nonadherence rates of 15% vs 30%. Although a meta-analysis found an attrition rate of 7.4% in telephone psychotherapy, 15% was used because heterogeneity was high and many trials were small. Attributon of 30% and greater is commonly observed in trials of face-to-face psychotherapy. Differences in baseline characteristics by treatment group, nonadherence rates, treatment preference, and post-treatment major depressive disorder were analyzed with \( t \) tests for continuous variables and \( \chi^2 \) tests for categorical variables.

Although the rate of missing depression outcomes was low at each post-baseline point, ranging from 9% to 22%, we multiplied imputed missing depression scores and generated 20 imputations for each missing value, using the R package MICE, in which incomplete variables are imputed one at a time according to a set of conditional densities. Imputations were conducted separately by treatment group, and every imputation model was conditioned on a large number of relevant variables, including depression scores, demographics, and total number of CBT sessions attended. Using an imputation model that includes many auxiliary variables preserves relationships among variables and provides more precise and accurate imputations. In particular, by including the number of CBT sessions attended, we were able to preserve the relationship between amount of treatment received and depression symptoms among patients with missing depression scores.

Longitudinal depression scores were modeled with repeated-measures linear regression models as implemented in the SAS procedure PROC MIXED (version 9.02). Time was treated as a categorical variable to account for nonlinear effects of time, and an unstructured covariance matrix was assumed. Differences by treatment group in major depressive disorder and remission at 3- and 6-month follow-up were assessed with logistic regression, as was treatment response. These analyses were performed on each of the 20 imputed data sets and results were combined by using the rules of Rubin. During the trial, the data and safety monitoring board recommended changes in the planned analyses to replace the originally proposed analyses with a noninferiority analysis for depression outcomes. The noninferiority margin was not determined before the initiation of the trial, but it was determined before any analyses of outcome data and with the full knowledge and approval of oversight bodies. Noninferiority is established by showing that the true difference between 2 treatment arms is likely to be smaller than a prespecified noninferiority margin that separates clinically important from clinically negligible (acceptable) differences.

The clinical community has generally accepted 30% to 50% of the difference between treatment and control conditions as an acceptable definition for the noninferiority margin, and noninferiority trials of pharmalogic treatments have used the 50% criterion. A recent meta-analysis of CBT found an overall effect size of \( d = 0.82 \). Accordingly, we used \( d = 0.41 \) as the noninferiority criterion. A 1-sided test at \( \alpha = .05 \) of whether the difference in treatment groups is less than the noninferiority margin is equivalent to testing whether a 2-sided 90% CI around the treatment difference falls within the noninferiority margin. Accordingly, we calculated 90% CIs and rejected the null hypothesis of inferiority (in favor of
noninferiority) if the upper bound of the CI was less than $d = 0.41$.

To assess variable antidepressant use across treatment arms, a repeated-measures analysis of the binary antidepressant use outcomes over time was performed. To evaluate whether antidepressant use had differential effects by treatment group, antidepressant use and its interaction with treatment was included in our repeated-measures regression models for Ham-D and PHQ-9.

**RESULTS**

The flow of patients through the study is depicted in the Figure. Table 1 summarizes the baseline demographics and psychiatric characteristics of the participants. There were no significant differences in these baseline variables across treatment arms. There was no significant difference in therapist expectations of participant outcomes across treatments ($P = .83$).

### Attrition

Significantly fewer participants discontinued T-CBT ($n = 34$; 20.9%) before session 18 compared with face-to-face CBT ($n = 53$; 32.7%; $P = .02$). Attrition before week 5 was significantly lower in T-CBT ($n = 7$; 4.3%) than in face-to-face CBT ($n = 21$; 13.0%; $P = .006$), but there was no significant difference in attrition between sessions 5 and 18 ($P = .31$). T-CBT patients attended significantly more sessions (mean, 15.5; median, 17; SD, 4.4; interquartile range, 16-18) than those receiving face-to-face CBT (mean [SD], 13.7 [6.1]; median [IQR], 17 [11-18]; $P = .003$).

### Depression Outcomes

Table 2 shows the intention-to-treat depression outcomes on the Ham-D and the PHQ-9 according to multiply imputed values. In terms of changes from baseline, patients demonstrated significant improvements at posttreatment in both face-to-face (Ham-D $\Delta = -10.32$; PHQ-9 $\Delta = -10.03$; $P < .001$) and T-CBT (Ham-D $\Delta = -9.25$; PHQ-9 $\Delta = -10.12$; $P < .001$). At 6-month follow-up, changes from baseline remained significant in face-to-face CBT (Ham-D $\Delta = -10.69$; PHQ-9 $\Delta = -10.46$; $P < .001$) and T-CBT (Ham-D $\Delta = -7.78$; PHQ-9 $\Delta = -8.35$; $P < .001$). There were no significant posttreatment differences between T-CBT and face-to-face CBT on the Ham-D (difference $= 1.07$; $P = .22$) or PHQ-9 (difference $= -0.09$; $P = .89$), although this difference was significant at 6-month follow-up on both the Ham-D (difference $= 2.91$; $P < .001$) and PHQ-9 (difference $= 2.12$; $P = .004$).

Among T-CBT patients, 23% met criteria for major depressive disorder at posttreatment compared with 25% in face-to-face CBT ($P = .69$). At 6-month follow-up, major depressive disorder rates were 29% and 26% in the T-CBT and face-to-face CBT groups, respectively ($P = .57$). At posttreatment, 27% of both T-CBT and face-to-face CBT participants met the Ham-D abbreviated 7-item scale criterion for full remission ($P = .95$). By 6-month follow-up, 19% of T-CBT vs 32% of face-to-face CBT participants were fully remitted ($P = .009$). At posttreatment, 44% of T-CBT and 49% of face-to-face CBT participants met the response to treatment criterion of a 50% decrease on the HAM-D ($P = .40$).

The posttreatment effect size was $d = 0.14$ (90% CI $-0.05$ to $0.33$) on the Ham-D and $-0.02$ (90% CI $-0.20$ to $0.17$) on the PHQ-9. Both of these values were within the inferiority margin of $d = 0.41$, indicating that T-CBT was not inferior to face-to-face CBT at the end of treatment. The 6-month follow-up effect size was $d = 0.37$ (90% CI $0.19$-$0.55$) on the Ham-D and $0.33$ (90% CI $0.14$-$0.52$) on the PHQ-9. Both of these CIs were outside the inferiority margin, indicating that T-CBT was inferior to face-to-face CBT at 6-month follow-up.

### Antidepressant Effects

At baseline, 52 (32%) face-to-face CBT patients and 54 (33%) T-CBT patients were receiving antidepressants. During the course of the study, antidepressant use did not change significantly ($P = .41$), was not different across treatment arms ($P = .70$), and was not associated with depression outcomes in either the face-to-face CBT ($P = .92$) or T-CBT ($P = .83$) patients. Baseline antidepressant use was also not associated with discontinuation of treatment in either face-to-face CBT ($P = .29$) or T-CBT ($P = .91$).

### Patient Preferences

Before randomization, 117 (36.6%) participants indicated they would prefer face-to-face CBT, 89 (27.8%) preferred T-CBT, and 5 did not answer ($P = .60$). Receiving or not receiving one's preferred treatment was not statistically associated with adherence ($P = .39$) or depression outcomes ($P = .76$ for Ham-D; $P = .18$ for PHQ-9).

### Demographic Predictors of Clinical Outcomes and Attrition

There were no significant 2-way (demographic $\times$ treatment) or 3-way (demographic $\times$ treatment $\times$ time) effects for age, sex, race, education, or marital status on depression. Age, sex, race, marital status, and antidepressant status at baseline were unrelated to attrition. Education was significantly related to attrition ($P = .02$); participants with advanced degrees were more likely to complete treatment than those with some college education ($P < .05$), but there were no other significant differences across education groups.

### Safety

There were no adverse events (eg, suicide, suicide attempt, psychiatric hospitalization) for either treatment condition.

### COMMENT

This study confirmed that T-CBT produces significantly lower attrition rates compared with face-to-face CBT among depressed primary care patients, suggesting that telephone delivery can overcome barriers to adhering to face-to-face treatment. The effect of telephone administration on adherence appears to occur during the initial engagement period. These effects may be due to the capacity of telephone delivery to overcome barriers and patient ambivalence toward treatment. Access barriers likely exert their effects early in treatment, and thus the effect of the telephone on overcoming those barriers is most prominent in the first sessions. Patients who continue in face-to-face treatment for 5 or more sessions likely have fewer access barriers or are more motivated, and thus use of the telephone likely reduces attrition less during that period.

This trial found that T-CBT was as effective in reducing depressive symptoms as traditional face-to-face CBT at posttreatment, supporting our hypothesis. However, face-to-face treatment was significantly superior to T-CBT during the 6-month follow-up period. The size of these differences in group analyses did not reach the PHQ-9 criterion of 5 or more points for clinical significance but was close to the Ham-D criterion of 3 points.

It is likely that these effects are driven by subgroups who show greater risk of failure to maintain
therapeutic gains. This effect may be an artifact of T-CBT’s capacity to differentially retain patients with characteristics that leave them at greater risk for posttreatment deterioration.

If the finding that face-to-face treatment produces better maintenance of gains after treatment cessation is not an artifact, it suggests that longer-term follow-up is critical in research examining the effects of tele–mental health interventions, and telemedicine more broadly. There are at least 2 possible reasons that some patients may have poorer post-treatment outcomes in T-CBT. One is that the requirement that patients in face-to-face therapy physically attend sessions may serve as a form of behavioral activation. That is, that act of physically attending treatment may be therapeutic in a manner that promotes maintenance of gains in some patients. The other possibility is that the physical presence of the therapist, although not having an effect during treatment, contributes to the maintenance of gains, which suggests that human contact may have unique qualities that exert their effects and contribute to resilience after contact has ceased.

The patient-clinician interaction can be conceptualized as a variety of cues and information transmitted through different verbal and nonverbal channels, each of which carries some unique information. Various telemedicine media (eg, telephone, videoconference, e-mail) limit the effectiveness of specific cues, which may have both disadvantages and benefits. For example, in the context of a positive relationship, individuals are likely to make positive attributions in the absence of cues (for example in the absence of visual cues, patients would likely imagine a provider as being more like themselves and more sympathetic than the provider actually is). However, if difficulties or suspicions arise, attributions regarding missing cues can become overly negative (eg, imagining the clinician to be more uncaring than a complete set of cues would suggest), which may reduce the patient’s commitment to treatment. Thus, future research should not only examine overall effects of the use of treatment delivery media on patient-clinician relationships and clinical outcomes but also identify the circumstances and patients for which specific media are most advantageous.

The findings of this study suggest that telephone-delivered care has both advantages and disadvantages. The acceptability of delivering care over the telephone is growing, increasing the potential for individuals to continue with treatment. A survey of primary care patients found that nearly 19% of patients who desired behavioral and psychological care wanted telephone treatment, and an additional 44% would consider it. The data from this trial suggest that preferences for delivery medium do not affect adherence or outcome. The telephone offers the opportunity to extend care to populations that are difficult to reach, such as rural populations, patients with chronic illnesses and disabilities, and individu-

Abbreviations: CBT, cognitive behavioral therapy; Ham-D, Hamilton Depression Rating Scale; PHQ-9, Patient Health Questionnaire-9; T-CBT, telephone cognitive behavioral therapy.

<sup>a</sup>These are values based on parameter estimates from the mixed-effects models and use multiply imputed data from all time points to predict means at each point.

<sup>b</sup>The Ham-D range is 0 to 52. A difference of 3 points on the Hamilton scale has been identified as clinically significant.

<sup>c</sup>The PHQ-9 range is 0–27. A difference of 5 or more points on the PHQ-9 is considered a clinically meaningful response to treatment.
Telephone vs In-Person Therapy for Depression

als who otherwise have barriers to treatment.14,30 Telephone psychotherapy would also meet at least 1 of the key attributes of the advanced medical home, namely, to “provide enhanced and convenient access to care not only through face-to-face visits but also via telephone, e-mail, and other modes of communication.”30 However, the increased risk of posttreatment deterioration in telephone-delivered treatment relative to face-to-face treatment underscores the importance of continued monitoring of depressive symptoms even after successful treatment.

Several limitations and caveats exist in interpreting these data. First, this efficacy trial used CBT for depression. Although we are unaware of reasons why these results cannot be generalized to other forms of psychotherapy and other common mental health problems such as anxiety disorders, we cannot rule out the possibility that these findings are treatment or disorder specific. Second, this sample was fairly well educated, potentially limiting generalizability to lower socioeconomic groups. Third, it was not possible to mask patients to treatment arm.

Our findings demonstrate that T-CBT can reduce attrition and is as effective as face-to-face CBT at posttreatment for depression among primary care patients. However, the increased adherence associated with T-CBT may come at the cost of some increased risk of poorer outcomes after treatment cessation.
