Dietary Fiber Intake and Risk of Colorectal Cancer
A Pooled Analysis of Prospective Cohort Studies

Context Inconsistent findings from observational studies have continued the controversy over the effects of dietary fiber on colorectal cancer.

Objective To evaluate the association between dietary fiber intake and risk of colorectal cancer.

Design, Setting, and Participants From 13 prospective cohort studies included in the Pooling Project of Prospective Studies of Diet and Cancer, 725,628 men and women were followed up for 6 to 20 years across studies. Study- and sex-specific relative risks (RRs) were estimated with the Cox proportional hazards model and were subsequently pooled using a random-effects model.

Main Outcome Measure Incident colorectal cancer.

Results During 6 to 20 years of follow-up across studies, 8,081 colorectal cancer cases were identified. For comparison of the highest vs lowest study- and sex-specific quintile of dietary fiber intake, a significant inverse association was found in the age-adjusted model (pooled RR=0.84; 95% confidence interval [CI], 0.77-0.92). However, the association was attenuated and no longer statistically significant after adjusting for other risk factors (pooled multivariate RR=0.94; 95% CI, 0.86-1.03). In categorical analyses compared with dietary fiber intake of 10 to <15 g/d, the pooled multivariate RR was 1.18 (95% CI, 1.05-1.31) for less than 10 g/d (11% of the overall study population); and RR, 1.00 (95% CI, 0.85-1.17) for 30 or more g/d. Fiber intake from cereals, fruits, and vegetables was not associated with risk of colorectal cancer. The pooled multivariate RRs comparing the highest vs lowest study- and sex-specific quintile of dietary fiber intake were 1.00 (95% CI, 0.90-1.11) for colon cancer and 0.85 (95% CI, 0.72-1.01) for rectal cancer (P for common effects by tumor site = .07).

Conclusions In this large pooled analysis, dietary fiber intake was inversely associated with risk of colorectal cancer in age-adjusted analyses. However, after accounting for other dietary risk factors, high dietary fiber intake was not associated with a reduced risk of colorectal cancer.

DIETARY FIBER AND COLORECTAL CANCER RISK

the other hand, most prospective co-
hort studies have found no associa-
tion between dietary fiber intake and
risk of colorectal cancer3-7 or adeno-
mas (precursors of colorectal can-
cer),8 and randomized clinical trials of
dietary fiber supplementation have failed to show reductions in the recur-
rence of colorectal adenomas.9-12 Re-
cently, the European Prospective In-
vestigation into Cancer and Nutrition
(EPIC) study and the Prostate, Lung,
Colorectal, and Ovarian Cancer Screen-
ing Trial observed a statistically signifi-
cant 25% lower risk of colorectal can-
cer13,14 or adenomas,15 respectively, in
the highest quintile of dietary fiber in-
take compared with the lowest. Be-
cause of these discordant results, the
debate continues on whether dietary fiber consumption decreases colorectal cancer risk. In this study, we evaluated the association between dietary fiber intake and risk of colorectal cancer by re-
analyzing the primary data from 13 pro-
spective cohort studies.

**METHODS**

**Study Population**

The Pooling Project of Prospective Studies of Diet and Cancer (Pooling Project) was established to suma-
rize the association between dietary fac-
tors and risk of cancers, and the de-
tails of the Pooling Project have been
described previously.16 For the colo-
rectal cancer analyses, we identified 13
prospective cohort studies1,6,17-25 that
met the following inclusion criteria: (1)
at least 50 incident colorectal cancer
cases; (2) assessment of usual dietary
intake; (3) completion of a validation
study-specific loge RRs by the inverse of the
quintiles, as well as to categories de-
efined by absolute intake cut points that
were identical across studies. We per-
formed study- and sex-specific age-
adjusted and multivariate analyses. The
proportion of missing values for each covariate measured in a study was gen-
erally less than 5%; an indicator vari-
able for missing responses was cre-
ated for each covariate in a study if
needed. The test for trend across cat-
ergories of intake was performed by as-
signing participants the median value of their category and entering those val-
ues as a continuous term in a regres-
sion model.

The pooled estimates and 95% CIs
were calculated using a random-effects
model that weighted individual study-
specific log., RR by the inverse of the
sum of their variance. Between-studies
heterogeneity was tested by the Q sta-
tistic.43 Differences in results among tu-
ror sites were tested by the Wald test
statistic.44 A meta-regression model was
used to test for variation in RR by sex,
geographical location of the study, and
follow-up time.45

In addition, we evaluated whether di-
etary fiber intake was log-linearly asso-
ciated with risk of colorectal cancer by
comparing the nonparametric regres-
sion curve obtained using restricted cu-
ic splines with the linear model using
the likelihood ratio test and by visual in-

**Case Ascertainment**

Incident colorectal cancer cases were
identified by each cohort through self-
administered questionnaires with sub-
sequent medical record review,3,17-21
linkage with a cancer registry,4,17-21 or
both.5,6,23,24 Some studies also had an addi-
tional linkage with a death regist-
try.3,22,25 The follow-up rate of these
studies was generally over 90%.

**Statistical Analysis**

In addition to applying the exclusion-
ary criteria used by each study, we also
excluded individuals from the analys-
eses who had a history of cancer other
than nonmelanoma skin cancer at base-
line and who reported implausible en-
ergy intakes (beyond 3 SDs from the
mean intake).

Data analyses comprised study- and
sex-specific analyses and subsequent
pooled analyses of the study-specific re-
sults. Study- and sex-specific relative
risks (RRs) and 2-sided 95% confi-
dence intervals (CIs) were estimated
with the Cox proportional hazards
model.38 SAS statistical software (ver-
sion 8, SAS Institute Inc, Cary, NC)39
was used for all studies except the Ca-
nadian National Breast Screening Ex-
study and the Netherlands Cohort Study, which were analyzed as case-cohort
studies40 using Epicure software (ver-
sion 2.11, HiroSoft International Corp,
Seattle, Wash).41 Age at baseline (in
years) and the year when the baseline
questionnaire was returned were used
as stratification variables, thereby cre-
ating a time metric that simulta-
neously accounted for age, calendar
time, and time after entry into the study.

Person-years of follow-up time were
calculated from the date of the baseline
questionnaire until the date of colorec-
tal cancer diagnosis, death, or end of
follow-up, whichever came first. The
person-time experienced during the fol-
low-up of the Nurses' Health Study was
divided into 2 asymptotically uncorre-
lated segments42 to take advantage of
the more detailed dietary assessment in
1986. The RRs of colorectal cancer were
estimated according to study-specific
quintiles, as well as to categories de-
finite by absolute intake cut points that
were identical across studies. We per-
formed study- and sex-specific age-
adjusted and multivariate analyses. The
proportion of missing values for each covariate measured in a study was gen-
erally less than 5%; an indicator vari-

able for missing responses was cre-
ated for each covariate in a study if
needed. The test for trend across cat-
ergories of intake was performed by as-
signing participants the median value of their category and entering those val-
ues as a continuous term in a regres-
sion model.

The pooled estimates and 95% CIs
were calculated using a random-effects
model that weighted individual study-
specific log., RR by the inverse of the
sum of their variance. Between-studies
heterogeneity was tested by the Q sta-
tistic.43 Differences in results among tu-
ror sites were tested by the Wald test
statistic.44 A meta-regression model was
used to test for variation in RR by sex,
geographical location of the study, and
follow-up time.45

In addition, we evaluated whether di-
etary fiber intake was log-linearly asso-
ciated with risk of colorectal cancer by
comparing the nonparametric regres-
sion curve obtained using restricted cu-
ic splines with the linear model using
the likelihood ratio test and by visual in-
spection of the restricted cubic spline graphs. For this analysis, all studies were combined into a single data set stratified by study, and the number and location of the knots were identified through a stepwise selection process.

The effect of misclassification of dietary fiber intake was evaluated by the method developed by Zucker and Spiegelman.

RESULTS

During follow-up times of 6 to 20 years in 13 cohort studies, 7,328,414 person-years were accumulated and 8,081 incident colorectal cancer cases were identified (2,776 men and 5,305 women; 572 colon cancer and 2,188 rectal cancer cases plus 167 site unspecified). Among the studies, median energy-adjusted dietary fiber intake ranged from 14 to 28 g/d in men and from 13 to 24 g/d in women. The major source of dietary fiber varied across studies with cereals as a major contributor to dietary fiber intake in the European studies, and fruits and vegetables as the main sources in the North American studies (Table 1).

Comparing the Highest vs the Lowest Quintile of Dietary Fiber Intake

Figure 1.

Table 2. Pooled Relative Risks of Colorectal Cancer for Quintiles of Dietary Fiber Intake

in women). The association between dietary fiber intake and risk of colorectal cancer was not significantly modified by sex or age at diagnosis; compared with the lowest quintile the pooled multivariate RR for the highest quintile was 0.96 (95% CI, 0.82-1.13) for men; 0.93 (95% CI, 0.83-1.04) for women; (P for between-studies heterogeneity due to sex = .74); 0.96 (95% CI, 0.82-1.12) for cases diagnosed in patients younger than age 65 years (3048 cases); and 0.92 (95% CI, 0.79-1.06) for patients diagnosed at age 65 years and older (5033 cases). We also found no statistically significant differences in the association between dietary fiber intake and colorectal cancer risk by body mass index (calculated as weight in kilograms divided by the square of height in meters), smoking, alcohol consumption, and red meat intake (data not shown). In addition, the results were similar in European and North American studies: the pooled multivariate RR in the highest quintile vs the lowest was 0.99 (95% CI, 0.80-1.23) for the European studies and 0.92 (95% CI, 0.83-
1.02) for the North American studies (P for difference = 0.45).

To examine whether the association between dietary fiber intake and risk of colorectal cancer was modified by length of follow-up, we performed separate analyses for cases diagnosed within the first 5 years of follow-up and for cases diagnosed at least 5 years after their baseline assessment. When follow-up time was limited to only the first 5 years, there was a suggestion of an inverse association (pooled multivariate RR = 0.87; 95% CI, 0.76-1.00 in the highest quintile vs the lowest; 3257 cases). However, after a 5-year latency period between the baseline diet assessment and outcome ascertainment, no association was observed (pooled multivariate RR = 1.00; 95% CI, 0.89-1.12 in the highest quintile vs the lowest; 4824 cases).

In categorical analyses using identical absolute intake cut points across studies, the pooled age-adjusted RR was 0.90 (95% CI, 0.75-1.08) and the pooled multivariate RR was 1.00 (95% CI, 0.85-1.17) (TABLE 3) for comparisons of dietary fiber intake of 30 or more g/d vs 10 to less than 15 g/d. However, the pooled multivariate RR was significantly elevated (RR = 1.18; 95% CI, 1.05-1.31) among individuals with dietary fiber intake less than 10 g/d (11% of the overall study population) compared with 10 to less than 15 g/d. Because the association between dietary fiber intake and risk of colorectal cancer was non-linear, we calculated measurement error corrected RRs for comparisons of less than 10 g/d vs 10 or more g/d. For this comparison, the strongest confounder was smoking status. Among the studies that had colorectal cancer cases with dietary fiber intake of less than 10 g/d, measured smoking status, and had a sufficient range of dietary fiber intake in their validation study to perform the misclassification analysis, correction for misclassification of dietary fiber intake strengthened the association: the pooled age and smoking adjusted RR comparing less than 10 g/d vs 10 or more g/d of dietary fiber intake changed from 1.22 (95% CI, 1.10-1.35) to 2.16 (95% CI, 1.12-4.16) after correction for measurement error.

The nonparametric regression curve obtained after combining all studies into a single data set showed a pattern similar to the categorical analyses in which study-specific RRs were pooled (FIGURE 2): the multivariate RR declined with increasing dietary fiber intake up to about 15 g/d, but then flattened out (P for nonlinearity = 0.05).

There was a suggestion that the association with dietary fiber intake differed by tumor site (P for common effects by tumor site for the highest quintile = 0.07) (Table 2). Comparing the highest vs lowest quintile of intake, a

*For the highest category.
†For the colorectal and colon cancer analyses, the Netherlands Cohort Study and the New York State Cohort were excluded from the <10 g/d category because these studies did not have any cases in that category; ORDET was excluded from the ≥30 g/d category because this study did not have any cases in that category; 1.05 for adjustment for age; body mass index (calculated as weight in kilograms divided by the square of height in meters) (≥23, ≥25, ≥30, ≥30; height; men: ≥1.70, ≥1.70, ≥1.75, ≥1.75; ≥1.80, ≥1.80, ≥1.85, ≥1.90; women: ≥1.60, ≥1.60, ≥1.65, ≥1.70, ≥1.70, ≥1.75, ≥1.85; ≥1.90; education (<high school graduate, high school graduate, >high school graduate); physical activity (low, medium, high); family history of colorectal cancer (no, yes); use of postmenopausal hormone therapy (premenopausal, never, ever); oral contraceptive use (never, ever), use of nonsteroidal anti-inflammatory drugs (no, yes); multivitamin use (no, yes <6 times/wk, yes ≥6 times/wk); missing dose in the Breast Cancer Detection Demonstration Project Follow-up Study, Health Professionals Follow-up Study, Iowa Women’s Health Study, Nurses’ Health Study [a and b], and Women’s Health Study; no, yes, for the Alphatocopherol Beta-carotene Cancer Prevention Study, Cancer Prevention Study II Nutrition Cohort, Netherlands Cohort Study, and New York State Cohort; smoking habits (never, past [<20y, 20–<40y, ≥40y], current: ≤<25 cigarettes/d and <40y, >25 cigarettes/d and ≥40y, ≤<25 cigarettes/d and <40y, >25 cigarettes/d and ≥40y), alcohol (g/d, ≥0.40 g/d, >0.40 g/d, >0.40 g/d, ≥0.40 g/d, >0.40 g/d, >0.40 g/d), dietary intake of fat (quintiles), red meat (quintiles), total milk (quintiles), total energy (continuous).
§For the rectal cancer analyses, the highest category of dietary fiber intake is defined as ≥25 g/d due to small numbers of cases with higher intakes. For the rectal cancer analyses, the Netherlands Cohort Study, New York State Cohort, and ORDET were excluded from the <10 g/d category because these studies did not have any cases in that category; the Cancer Prevention Study II Nutrition Cohort was excluded from the ≥25 g/d category because this study did not have any cases in that category; and the male cohort of the New York State Cohort was excluded from the rectal cancer analyses because this study had no cases in the reference group.

©2005 American Medical Association. All rights reserved.
null association was found for colon cancer (pooled multivariate RR=1.00; 95% CI, 0.90-1.11), whereas a borderline-significant, weak inverse association was found for rectal cancer (pooled multivariate RR=0.85; 95% CI, 0.72-1.01). Further analyses of proximal colon cancer (pooled multivariate RR=1.05; 95% CI, 0.91-1.21) and distal colon cancer separately (pooled multivariate RR=0.96; 95% CI, 0.80-1.14) showed no statistically significant association (P for common effects by tumor site for the highest quintile = .24).

In analyses of the sources of dietary fiber, fiber intakes from cereals and fruits were each associated with approximately a 10% reduction in risk of colorectal cancer in the age-adjusted model comparing the highest quintile with the lowest (Table 4). However, after adjustment for potential colorectal cancer risk factors, the associations were attenuated and not statistically significant (pooled multivariate RR=1.00; 95% CI, 0.93-1.08 for fiber from cereals; pooled multivariate RR=0.96; 95% CI, 0.89-1.04 for fiber from fruits in the highest quintile vs the lowest). Dietary fiber from vegetables was not associated with risk of colorectal cancer in both the age-adjusted and multivariate models. When associations with specific sources of dietary fiber were examined by tumor site, we found that the associations with fiber intake from cereals were significantly different between colon and rectal cancer (P for common effect by tumor site for the highest quintile = .05), even though neither association was statistically significant. Comparing the highest vs the lowest quintile for fiber intake from cereals, the pooled multivariate RR was 0.91 (95% CI, 0.78-1.06, P for trend=.20) for rectal cancer, and 1.03 (95% CI, 0.94-1.13, P for trend=.90) for colon cancer. For fiber intake from fruits and from vegetables, no significant differences by tumor site were observed (data not shown).

Intakes of whole grain and refined grain food were each not statistically associated with risk of colorectal cancer: the pooled multivariate RR in the highest quintile vs the lowest were 0.92 (95% CI, 0.84-1.00, P for trend=.21) for whole grain food and 1.01 (95% CI, 0.91-1.13, P for trend=.94) for refined grain food. Although the results did not significantly differ by tumor site for both whole and refined grain food intake, there was a suggestion that whole grain food intake was inversely associated with risk of rectal cancer (pooled multivariate RR=0.81; 95% CI, 0.65-1.00 in the highest quintile vs the lowest, P for trend=.07). In the analyses of grain foods, if dietary folate intake was not included as a covariate, the results did not change.

**COMMENT**

In this pooled analysis of 13 prospective cohort studies, we observed a statistically significant inverse association between dietary fiber intake and risk of colorectal cancer in the age-adjusted model. However, the overall association was attenuated and no longer statistically significant after ad-

justing for other colorectal cancer risk factors. When intakes of dietary fiber were examined separately by specific food sources, none were associated with risk of colorectal cancer. However, there was a suggestion that intake of dietary fiber from cereals and intake of dietary fiber from whole grain foods were both associated with a weak reduction in risk of rectal cancer.

The association between dietary fiber intake and risk of colorectal cancer has been inconsistent among observational studies and several factors may explain the disparity: potential biases in each study, the failure to adjust for covariates in the multivariate models, and the range of dietary fiber intake. Inconsistent results also have been reported from randomized clinical trials of dietary fiber supplementation on the recurrence of colorectal adenomas (precursors of colorectal cancer); most trials have found no reduced risk of adenoma recurrence with dietary fiber supplementation compared with placebo, but one trial found a significantly increased risk of adenoma recurrence in the psyllium supplementation group. A statistically significant reduction in risk of colorectal cancer with higher dietary fiber intake has been observed in most case-control studies. However, case-control studies are prone to recall bias because dietary assessments are obtained after cancer diagnosis and also are prone to selection bias because control participants who participate are likely to be particularly health-conscious. In addition, publication bias may contribute to the accumulation of literature with significant findings. On the other hand, the Pooling Project is less susceptible to these biases because diet was assessed prior to diagnosis and the studies were not required to have published on the association between dietary fiber intake and risk of colorectal cancer.

The etiology of colorectal cancer has been studied extensively during the past few decades leading to the identification of many risk factors for colorectal cancer. Because earlier case-control studies did not adjust for recently identified colorectal cancer risk factors, reported associations with dietary fiber may have been confounded by factors for which no adjustment was made in the multivariate models. The different results observed among recent studies also may be explained, in part, by the selection of the covariates that were included in the multivariate models. Recently the EPIC study, a multicenter prospective cohort study with 10 European countries (n=519,978; 1721 cases), found a statistically significant 30% lower risk of colorectal cancer in the multivariate model adjusted for age, sex, weight, height, nonfat energy, energy from fat, and center (RR=0.70; 95% CI, 0.58-0.85 in the highest quintile vs the lowest). Additional adjustment for folate intake did not change the result (RR=0.68; 95% CI, 0.55-0.84), but noticeable attenuation was observed (RR=0.79; 95% CI, 0.63-0.99) after adjusting for other risk factors such as education, physical activity, alcohol, smoking, and red meat intake. In the Pooling Project, the inverse association observed between dietary fiber intake and risk of colorectal cancer in the age-adjusted model (RR=0.84; 95% CI, 0.77-0.92) (Table 2) was attenuated after adjusting for age, nondietary risk factors, multivitamin use, and energy intake, but remained statistically significant (pooled multivariate RR=0.88; 95% CI, 0.82-0.95) (Table 2, multivariate model I). However, further attenuation occurred after adjusting for dietary folate intake (pooled multivariate RR=0.92; 95% CI, 0.84-1.01) (Table 2, multivariate model II), but no observable attenuation was observed after adjusting for other dietary factors such as consumption of red meat, total milk, and alcohol intake (pooled multivariate RR=0.94; 95% CI, 0.86-1.03) (Table 2, multivariate model III). In our study, intake of folate was positively correlated with intake of dietary fiber, while intakes of red meat and total milk were inversely correlated with intake of dietary fiber, but the strength of correlations varied across studies. Intake of alcohol was positively correlated with intake of dietary fiber in some studies, but showed an inverse correlation in other studies. Because the degree of confounding by other risk factors of colorectal cancer may vary depending on characteristics of a study population, thorough examination for selection of covariates to be included in a multivariate model is needed.

The range of dietary fiber intake reported within a study may be another factor that has contributed to different findings among studies. If the range of intake of a nutrient in a study is very narrow, a null association may be more likely observed. However, lack of variation in dietary fiber intake is unlikely to have accounted for the null association we found. In our analyses, the study-specific mean energy-adjusted dietary fiber intake was 9 to 20 g/d for men and 8 to 17 g/d for women in the lowest quintile and 23 to 41 g/d for men and 20 to 35 g/d for women in the highest quintile with a 1.8- to 3.0-fold difference in intakes between the 2 extreme quintiles across studies. This range is similar to the range observed in EPIC, which reported a statistically significant inverse association with dietary fiber intake. Mean dietary fiber intake in EPIC was 18 g/d for men and 16 g/d for women in the lowest quintile and 30 g/d for men and 24 g/d for women in the highest quintile (a 1.5- to 1.7-fold difference). In addition, when we used identical absolute intake cut points across studies, no association was observed for dietary fiber intake of at least 30 g/d vs 10 to less than 15 g/d, which is similar to the quintile definitions used in EPIC.

Because the Pooling Project is a retrospectively planned pooled analysis of the primary data, the food frequency questionnaires that were used to assess diet varied across studies. To take into account potential misclassification in dietary fiber intake that may arise from measurement error in energy intake, we calculated energy-adjusted intakes for each study. We also conducted analyses by categorizing dietary fiber intake using study-specific quin-
tiles and identical absolute intake cut points across studies. In the study-specific quintile analyses, true differences in population intakes were not taken into account, potentially resulting in misclassification of dietary fiber intake in the pooled results. However, misclassification could also have occurred in the analyses based on identical absolute intake cut points because dietary fiber intakes may vary across studies due to differences in the accuracy in which the food frequency questionnaires estimated dietary fiber. Despite the different potential for misclassification between these 2 analytic approaches, both showed no association between dietary fiber intake and risk of colorectal cancer above the lowest category of dietary intake.

Several limitations of our analysis should be considered. Fiber intake is likely to be measured with error because of errors in how study participants estimate their consumption of fiber-containing foods and by errors in the food composition databases. A true association between dietary fiber intake and risk of colorectal cancer may be underestimated in our study. In addition, although we were able to correct for misclassification of dietary fiber intake at baseline, the single assessment of dietary fiber intake in our analysis may not reflect long-term usual intake as accurately as using repeated measurements of dietary intake during follow-up. However, the use of repeated measurements of dietary fiber intake in the Nurses' Health Study did not change substantially the relationships, confounding, and effect modification than meta-analyses of the published literature, which frequently summarize risk estimates obtained for heterogeneous exposure categories with different adjustment for potential founders. Also, we had high statistical power with over 8000 colorectal cancer cases, thus a substantial effect of fiber is unlikely to have been missed. In addition, in a subset of the studies we were able to correct for measurement error in dietary fiber intake using their validation study data. Our ability to correct for measurement error strengthened the estimated association observed between very low dietary fiber intake and colorectal cancer risk; however, it should be noted that in this analysis we could only adjust for age and smoking, the 2 strongest confounders in the multivariate analysis when comparing less than 10 vs 10 g/d or more of dietary fiber intake.

In conclusion, we did not find support for a linear inverse association between dietary fiber intake and risk of colorectal cancer in a pooled analysis of 13 prospective cohort studies. Although high dietary fiber intake may not have a major effect on the risk of colorectal cancer, a diet high in dietary fiber from whole plant foods can be advised because this has been related to lower risks of other chronic conditions such as heart disease and diabetes.
