Effect of Homocysteine Lowering on Mortality and Vascular Disease in Advanced Chronic Kidney Disease and End-stage Renal Disease: A Randomized Controlled Trial

**Context** High plasma homocysteine levels are a risk factor for mortality and vascular disease in observational studies of patients with chronic kidney disease. Folic acid and B vitamins decrease homocysteine levels in this population but whether they lower mortality is unknown.

**Objective** To determine whether high doses of folic acid and B vitamins administered daily reduce mortality in patients with chronic kidney disease.

**Design, Setting, and Participants** Double-blind randomized controlled trial (2001-2006) in 36 US Department of Veterans Affairs medical centers. Median follow-up was 3.2 years for 2056 participants aged 21 years or older with advanced chronic kidney disease (estimated creatinine clearance ≤ 30 mL/min) (n = 1305) or end-stage renal disease (n = 751) and high homocysteine levels (≥ 15 μmol/L).

**Intervention** Participants received a daily capsule containing 40 mg of folic acid, 100 mg of pyridoxine hydrochloride (vitamin B6), and 2 mg of cyanocobalamin (vitamin B12) or a placebo.

**Main Outcome Measures** The primary outcome was all-cause mortality. Secondary outcomes included myocardial infarction (MI), stroke, amputation of all or part of a lower extremity, a composite of these 3 plus all-cause mortality, time to initiation of dialysis, and time to thrombosis of arteriovenous access in hemodialysis patients.

**Results** Mean baseline homocysteine level was 24.0 μmol/L in the vitamin group and 24.2 μmol/L in the placebo group. It was lowered 6.3 μmol/L (25.8%; P < .001) in the vitamin group and 0.4 μmol/L (1.7%; P = .14) in the placebo group at 3 months, but there was no significant effect on mortality (448 vitamin group deaths vs 436 placebo group deaths) (hazard ratio [HR], 1.04; 95% CI, 0.91-1.18). No significant effects were demonstrated for secondary outcomes or adverse events: there were 129 MIs in the vitamin group vs 150 for placebo (HR, 0.86; 95% CI, 0.67-1.08), 37 strokes in the vitamin group vs 41 for placebo (HR, 0.90; 95% CI, 0.58-1.40), and 60 amputations in the vitamin group vs 53 for placebo (HR, 1.14; 95% CI, 0.79-1.64). In addition, the composite of MI, stroke, and amputations plus mortality (P = .85), time to dialysis (P = .38), and time to thrombosis in hemodialysis patients (P = .97) did not differ between the vitamin and placebo groups.

**Conclusion** Treatment with high doses of folic acid and B vitamins did not improve survival or reduce the incidence of vascular disease in patients with advanced chronic kidney disease or end-stage renal disease.

**Trial Registration** clinicaltrials.gov Identifier: NCT00032435

cardiovascular events or death in a variety of high-risk patients,11-13 although a post hoc analysis in one study showed that a subgroup of stroke patients might have benefited from the intervention.14

Patients with chronic kidney disease or end-stage renal disease (ESRD) have higher homocysteine levels than those in the foregoing trials.15-17 They have extensive vascular disease, with estimates of annual mortality as high as 20%.18-20 The cerebral and cardiovascular complications of the vascular disease, and, in some studies, thrombosis of the vascular access, a common and costly complication in ESRD,21 are correlated with high homocysteine levels.21

The characteristically high homocysteine levels, extensive vascular disease, and high mortality rates make this population particularly suitable to test the benefit of lowering homocysteine. We conducted a randomized controlled trial, sponsored by the Department of Veterans Affairs (VA) Cooperative Studies Program (Homocysteinemia in Kidney and End Stage Renal Disease [HOST]), to determine whether treatment with a combination of high-dose folic acid and vitamins B6 and B12 levels, can reduce mortality and cardiovascular events in patients with advanced chronic kidney disease (ACKD) and ESRD.

METHODS

Study Design

The details of the HOST study design have been described22 and are summarized here. HOST was a multicenter, randomized, double-blind, placebo-controlled trial to determine whether treatment with folic acid plus pyridoxine and cyanocobalamin to lower plasma total homocysteine levels reduces all-cause mortality and major vascular events in a high-risk population.

Study Population

Participants aged 21 years or older, with ESRD, receiving maintenance hemodialysis or peritoneal dialysis, or with an estimated creatinine clearance of less than or equal to 30 mL/min (to convert creatinine clearance to mL/s, multiply by 0.0167) by the Cockcroft-Gault formula23 (ACKD) were recruited from 36 participating VA medical centers. A plasma homocysteine level of 15 µmol/L or higher was also required. Race and ethnicity were based on patient self-report by using investigator-defined options. Race and ethnicity were assessed because they have been reported to be associated with the prevalence and outcomes of individuals with chronic kidney disease.

The human rights committee at the coordinating center and the institutional review boards of all participating sites approved the study, and all study participants provided written informed consent.

Study Intervention

Participants were randomly assigned to receive a once-daily capsule containing 40 mg of folic acid, 100 mg of pyridoxine hydrochloride, and 2 mg of cyanocobalamin or an identical-appearing placebo capsule. Participants, investigators, laboratory staff, and the Endpoint Adjudication Committee were blinded to treatment assignment. The randomization scheme was stratified by site and disease strata (ESRD vs ACKD) and used a random permuted block design of varying block size. Participants in both groups were allowed to take additional vitamins containing no more than 1 mg of folate, if prescribed by their physicians as part of their general medical care.

Baseline and Follow-up Evaluations

At entry, demographic, clinical, and laboratory data, including plasma homocysteine and serum folic acid and vitamins B6 and B12 levels, were obtained and participants were given a 3-month supply of study drug. Participants returned to the local sites for evaluation at 3 months. A fasting blood sample was collected for homocysteine and folate acid determination. Participants were asked about hospitalizations, medication adherence, study outcomes, and adverse events during the past 3 months and were given a new 3-month supply of study drug. All subsequent quarterly follow-up evaluations were conducted by telephone (or, if necessary, by mail or e-mail) by study coordinators located at 2 centers. The central study coordinators attempted to verify all study-related outcome events reported by the participants by searching the VA electronic records or by requesting records for non-VA hospitalizations. The participants received a quarterly supply of study capsules by mail from the VA Cooperative Studies Program Clinical Research Pharmacy. To assess adherence, participants were asked to return the bottle with unused capsules when they received a new bottle. In a representative substudy of 358 participants from 6 participating sites, blood samples were obtained annually for homocysteine, folic acid, vitamin B6, and vitamin B12 determinations. The sites were selected according to number of participants (3 smaller and 3 larger sites) and were geographically dispersed.

Trial Outcomes

The primary study outcome was time to death from any cause. Secondary outcomes included time to myocardial infarction (MI), stroke, amputation of all or part of a lower extremity, and a composite of these 3 plus all-cause mortality. In addition, we assessed time to thrombosis of arteriovenous access (fistula or graft) in hemodialysis patients and time to initiation of dialysis in ACKD patients. All participants continued to be followed up and to receive their assigned treatment after a secondary outcome event.

Deaths were confirmed by hospital discharge summary, autopsy report, Medicare End Stage Renal Disease Death Notification, or death certificate. Deaths were also tracked with the Beneficiary Identification and Records Locator Subsystem, a VA data file used to record death benefits and dates.24 Fatal and nonfatal events were ascertained through self-reporting by participants in response to specific queries during quarterly follow-up contacts and by review of the patient’s VA medical record. Myocardial infarction was diagnosed when 2 of the following 3 criteria were met: typical symptoms, increased cardiac enzyme levels, and diagnostic electrocardiographic changes.25 Stroke was defined as rapid onset of a persistent neurologic deficit attributed to an obstruction in the arterial system of the brain, providing the deficit was not known to be a result of cerebral hemorrhage, trauma, tumor, infection, or other nonthrombotic
causes. Thrombosis events were collected only for vascular accesses that were actually being used for dialysis and did not include events that occurred before dialysis initiation or that resulted in failure of access maturation.

An independent review committee, blinded to treatment assignment, adjudicated all secondary outcome events: MIs, strokes, and thromboses of the vascular access. Discharge summaries, neurologic examinations, imaging results, cardiac enzyme reports, and electrocardiograms were obtained to verify hospitalization, diagnosis, and outcomes. Only definite or probable events were included in the analysis. An independent data and safety monitoring board monitored the study for safety and scientific integrity.

**Laboratory Analyses**

Plasma homocysteine level was determined with the Fluorescence Polarization Immunoassay/Abbott Assym in kits provided by Abbott Laboratories (Abbot Park, Illinois). The determination of serum concentrations of folic acid and vitamin B12 (Bayer Direct Chemiluminescence Method [immunoassay]; Bayer Advia Centaur/Bayer Diagnostics, Tarrytown, New York) and vitamin B6 (Alpco REA; RKVB6, Salem, New Hampshire) was performed in a central chemistry laboratory.

**Statistical Analysis**

The study was designed to enroll 2006 patients, with a median follow-up of 5 years to detect a relative risk reduction in time to event for the primary outcome of 17%, with 80% power, given a loss rate of approximately 1% per year, an annual event rate of 10.3% in the placebo group, and a 2-sided type I error of .05. The target number of events was 820. All analyses were performed according to intention to treat. Participants who withdrew consent from all follow-up contacts and medical record reviews were included in the primary end point analysis but were censored from secondary outcome analyses at withdrawal. Survival curves for the 2 groups were estimated according to the Kaplan-Meier procedure and compared with the log-rank statistic. The hazard ratios (vitamins relative to placebo) for all primary and secondary outcomes were calculated with the Cox proportional hazards regression model, adjusted for strata (ACKD vs ESRD). Cox models were also used to evaluate the treatment effect on the primary outcome in the prespecified subgroups of age, race, diabetes history, cardiac disease history, renal disease strata, and baseline homocysteine levels. Treatment × subgroup interactions were performed to test for homogeneity. Additional sensitivity analyses of the treatment effect adjusted for baseline covariates were conducted to evaluate the stability of the study conclusions. All reported P values are 2-sided and unadjusted for multiple comparisons. P ≤ .05 was considered significant. SAS version 8.2 was used for all analyses (SAS Institute Inc, Cary, North Carolina).

**RESULTS**

Between September 2001 and October 2003, of the 2473 patients who consented for screening laboratory tests, 2056 participants—751 with ESRD and 1305 with ACKD—were randomized to the vitamin treatment (1032) or placebo groups (1024) (FIGURE 1). In May 2006, the data and safety monitoring board recommended that the study be stopped because the required number of primary end points had been reached. Patient...

(43.4%) in the treatment group and 436 (42.6%) in the placebo group. The cumulative 3-year mortality rate was 36.3% in the treatment group and 34.6% in the placebo group, with a mortality rate at 1 year of 11.8% vs 10.0%, respectively. After adjusting for the prespecified baseline covariates of age, race, smoking status, history of diabetes or cardiovascular disease, homocysteine, low-density lipoprotein cholesterol, and albumin, the effect of treatment was virtually un

Secondary End Points, Subgroups, and Adverse Events

Treatment had no effect on any of the major vascular events that comprise the secondary end points, the composite end point, the need to start maintenance dialysis, or thrombosis of the vascular access (Table 4). Vascular access thrombosis occurred in 73 of the 336 patients (22%) with fistulae and 101 of the 221 patients (46%) with grafts at baseline. All-cause mortality did not differ significantly between the treatment and placebo groups in any of the subgroups examined (FIGURE 3). The hazard ratio of treatment vs placebo for ACKD participants was 1.04 (95% CI, 0.88-1.23) and for ESRD participants, 1.04 (95% CI, 0.83-1.28) (P=.93). The mortality rates for the ACKD participants were 43.1% (placebo) vs 43.8% (treatment); for ESRD participants, 41.7% vs 42.7%, respectively.

There was no significant difference in the number and types of adverse events, including serious adverse events, between the treatment and control groups. There were no statistically significant differences between the treatment groups for any of the potential adverse effects of the vitamins that were specifically queried, including gastrointestinal and dermatological events, headache, paresthesia, and fatigue, or for any self-reported adverse events, or hospital admissions.

Adherence

Among patients assigned to the vitamin treatment group, 90.3% reported taking study medication at 1 year, 87.6% at 2 years, and 85.3% at 3 years. In the placebo group, the figures were similar: 90.7% at 1 year, 87.2% at 2 years, and 86.5% at 3 years. A total of 73% in the treatment group and 74% in the placebo group reported never stopping their study medication. Counts of capsules in the returned bottles (77% of those dispensed) revealed that 90% of study capsules were taken by patients in both treatment and placebo groups.

COMMENT

Patients with chronic kidney disease have a high risk for complications of atherosclerosis, including increased mor-
tality. Although traditional risk factors such as hypertension are more prevalent in this population, there has been increasing emphasis on the role of non-traditional risk factors such as anemia, hyperparathyroidism, and hyperhomocysteinemia. The association of elevated homocysteine levels with risk of cardiovascular disease has drawn attention because of the nearly universal elevation of homocysteine in patients with chronic kidney disease to levels higher than that of any other patient population except those with homocystinuria, the epidemiologic correlation between homocysteine and cardiovascular risk in the chronic kidney disease population, and the finding that ingestion of folic acid plus pyridoxine and cyanocobalamin lowers homocysteine levels in these patients.

The results of our trial, however, indicate that although administration of large daily doses of folic acid plus pyridoxine and cyanocobalamin to patients with ACKD or ESRD lowered plasma homocysteine levels, it did not improve survival during a median of 3.2 years of follow-up. Furthermore, there was no significant decrease in the incidence of cardiovascular events or, in hemodialysis patients, the rate of thrombosis of the vascular access, a common event requiring hospitalization in these patients.

Recent reports of several large randomized trials in lower-risk patients without kidney disease, in whom smaller doses of vitamins were used and smaller reductions in homocysteine levels were observed,

have failed to show a benefit of vitamin supplementation: the Vitamin Intervention for Stroke Prevention,\textsuperscript{13} the Heart Outcomes Prevention Evaluation (HOPE-2) study,\textsuperscript{12} and the Norwegian Vitamin (NORVIT) trial.\textsuperscript{11} Patients with kidney disease have higher plasma homocysteine levels and a higher risk for cardiovascular events than patients included in the previously cited trials. There have been a limited number of trials of homocysteine lowering in dialysis patients, but these trials were small and therefore underpowered to detect a clinically significant effect on mortality.\textsuperscript{31-33} In our trial, however, which used large doses of vitamins, resulting in a change in homocysteine levels twice that reported in previous trials,\textsuperscript{11-13} and was adequately powered to detect a relative risk reduction in mortality of 17%, we failed to find a benefit of vitamin supplementation. In contrast to the NORVIT study, we did not observe an increased risk of vascular events in the treatment group.\textsuperscript{11}

What might account for the failure of the treatment in our study? Possibly the underlying burden of disease was too great for a measurable benefit from lowering homocysteine. A trial of statins in diabetic dialysis patients failed to show a mortality benefit despite lowering low-density lipoprotein cholesterol,\textsuperscript{34} suggesting that even the reduction of some traditional risk factors may not be beneficial in this high-risk population. It may be that although homocysteine levels were substantially reduced, amelioration of the consequences of hyperhomocysteinemia requires lowering to normal levels, an effect that was achieved in only one-third of our participants, despite administration of the highest vitamin doses among homocysteine-lowering studies reported to date.\textsuperscript{35} Loscalzo,\textsuperscript{10} commenting on the results of the NORVIT and HOPE-2 trials, has suggested that vitamin therapy may have had adverse effects that offset its homocysteine-lowering benefit.

The disparity between our findings and the epidemiologic literature showing an association between moderate increases in homocysteine and atherothrombotic disease could reflect an unrecognized adverse effect of the folate acid or vitamins but in all probability reflects the inherent limitations of observational studies. It has been suggested that homocysteine marks the existence of vascular disease rather than causes it,\textsuperscript{10-13,32} yet in homocystinuria, vitamin therapy has an impressive benefit on mortality and cardiovascular events.\textsuperscript{3} It may be that the relationship between homocysteine and vascular injury is nonlinear or that the potential for amelioration of the vascular injury is too slight in patients without homocystinuria to be detectable, particularly in patients with many other risk factors.

There are several limitations of this study. First, the population was nearly all male. The relationship between homocysteine and vascular disease and the response to vitamin therapy is similar in men and women.\textsuperscript{2,5,36} The homocysteine levels and extent of vascular disease in the veterans in this trial are similar to those reported in nonveteran men and women with ACKD or ESRD\textsuperscript{16,18,32,33}; we would therefore not expect that the enrollment of a predominantly male population accounts for our null results. Second, to achieve adequate power we enrolled both ACKD and ESRD patients. Jungers et al\textsuperscript{36} reported an association of homocysteine and cardiovascular disease in chronic kidney disease similar to that in ESRD. In our study, homocysteine levels and prevalence of cardiovascular disease in the ACKD and ESRD strata were remarkably similar, as was the homocysteine-lowering effect of the vitamins. The proportion of participants who died during the study in the 2 groups was nearly identical. Although our study was not powered to examine these 2 strata separately, subgroup analyses did not show any difference in the treatment effect across strata. Third, follow-up contacts after the return visit at 3 months were not in person; thus, adherence and ascertainment of outcomes might have been incomplete. Previous studies have shown, however, that death can be reliably ascertained from death registries and patients’ electronic records within the VA health care system.\textsuperscript{74} Secondary outcomes of cardiovascular events may be less complete, but there is no a priori reason to expect differential ascertainment in the randomized groups.

In conclusion, treatment with high doses of folate acid and B vitamins did not reduce mortality or the incidence of cardiovascular events. Our findings do not support the administration of folate acid and B vitamin supplements to prevent vascular injury or improve survival in patients with ACKD or ESRD.

**Author Affiliations:** Veterans Affairs (VA) Palo Alto Health Care Systems and Division of Nephrology, Department of Medicine, Stanford University School of Medicine, Stanford, California (Dr Jamison); VA Cooperative Studies Program Coordinating Center, VA Connecticut Healthcare System, West Haven (Dr Hartigan and Guarino); Renal Section, VA Boston Healthcare System and Boston University School of Medicine, Boston, Massachusetts (Dr Kaufman); Nephrology Section, New York Harbor Healthcare System and New York University School of Medicine, New York, New York (Dr Goldfarb); VA Cooperative Studies Program, Clinical Research Pharmacy Coordinating Center and University of New Mexico College of Pharmacy, Albuquerque (Dr Warren); and Massachusetts Veteran’s Epidemiology Research and Information (MAVERIC), VA Boston Healthcare System, and Department of Medicine, Brigham and Women’s Hospital, Harvard Medical School, Boston (Dr Gaziano).

**Author Contributions:** Drs Jamison and Guarino had full access to all of the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. Study concept and design: Jamison, Hartigan, Kaufman, Goldfarb, Gaziano. Acquisition of data: Jamison, Hartigan, Kaufman, Warren, Guarino, Gaziano. Analysis and interpretation of data: Jamison, Hartigan, Kaufman, Goldfarb, Warren, Guarino, Gaziano. Drafting of the manuscript: Jamison, Kaufman, Goldfarb, Warren, Guarino. Critical revision of the manuscript for important intellectual content: Jamison, Hartigan, Kaufman, Goldfarb, Warren, Guarino, Gaziano. Statistical analysis: Hartigan, Guarino. Obtained funding: Jamison, Gaziano. Administrative, technical, or material support: Jamison, Hartigan, Kaufman, Goldfarb, Warren, Guarino, Gaziano. Other activities: Jamison, Hartigan, Kaufman, Goldfarb, Warren, Guarino, Gaziano.

**Financial Disclosures:** Dr Gaziano reported that in the past 5 years he has received investigator-initiated federal funding from the National Institutes of Health and the Department of Veterans Affairs, as well as non-federal investigator-initiated funding from McNeil Consumer Products, Amgen, and Veroscent. He also reported receiving research support and supplies from BASF, DMS Pharmaceuticals, and Wyeth Pharmaceuticals, receiving honoraria from Bayer and Pfizer for speaking engagements, serving as a consultant for McNeil Consumer Products, Wyeth Pharmaceuticals, and Bayer; and serving as an expert witness for Merck, Nutraquest, and GisaoSmithKline. No other authors reported financial disclosures.

**Events Adjudication Committee:** D. Forman, T. Gaziano, T. Kurth, D. Mesler. **Data and Safety Monitoring Board:** N. Levinsky (chair).
HOMOCYSTEINE LOWERING AND MORTALITY IN RENAL DISEASE

deceased], J. Koppel (chair), B. Brown Jr [deceased], A. Costello [deceased], T. Dieter Greene, M. Klag, A. Motulsky, T. Hostetter, P. Ridker.

vagato: E. Petrokaitis, S. Zellner.

Study Chair’s Office, VA Palo Alto Healthcare System, Palo Alto, California: A. Lindner, C. Stehman-Breen, E. Pascual, L. Titus; Palo Alto: R. Jamison, I. Cook, M. Anderson; Pitts-
burg: D. Smith, A. Renft, T. Finnigan; Richmond: G. Holmes; Kansas City: T. Wiegmann, J. Abdallah, A. Na-
vagato: E. Petrokaitis, S. Zellner.

Additional Contributions: We thank Ron Van Gronin-
gen, BS, VA Palo Alto HCS Chemistry Laboratory, for sub-
persisting the chemical analyses; and Philip Lavori, PhD, VA Palo Alto Cooperative Studies Program Coordinat-
ing Center, and Department of Health Research and Policy, Stanford University: David Tong, MD, California Pacific Medical Center Stroke Center, San Francisco; Paul Jungers, MD, Department of Neurology and Rehabilitation Medicine, Hôtel-Dieu, Paris, France; and Gere Sunder-Plassmann, MD, Klinische Ab-
teilung fur Nephrologie und Dialyse, Universitätssklinik für Innere Medizin III, University of Vienna, Vienna, Austria, for helpful advice and information. None of these indi-
viduals received compensation for their contributions.
