Association of Intravenous Radiocontrast With Kidney Function
A Regression Discontinuity Analysis

Robert Goulden, MBBS; Brian H. Rowe, MD; Michal Abrahamowicz, PhD; Erin Strumpf, PhD; Robyn Tamblyn, PhD

IMPORTANCE Radiocontrast has long been thought of as nephrotoxic; however, a number of recent observational studies found no evidence of an association between intravenous contrast and kidney injury. Because these studies are at high risk of confounding and selection bias, alternative study designs are required to enable more robust evaluation of this association.

OBJECTIVE To determine whether intravenous radiocontrast exposure is associated with clinically significant long-term kidney impairment, using a study design that permits stronger causal interpretation than existing observational research.

DESIGN, SETTING, AND PARTICIPANTS This cohort study included all emergency department patients aged 18 years or older undergoing D-dimer testing between 2013 and 2018 in the Canadian province of Alberta. A fuzzy regression discontinuity design was used, exploiting the fact that individuals just either side of the eligibility cutoff for computed tomographic pulmonary angiogram (CTPA)—typically 500 ng/mL—have markedly different probabilities of contrast exposure, but should otherwise be similar with respect to potential confounders.

EXPOSURES Intravenous contrast in the form of a CTPA.

MAIN OUTCOMES AND MEASURES Estimated glomerular filtration rate (eGFR) up to 6 months following the index emergency department visit.

RESULTS During the study period 156 028 individuals received a D-dimer test. The mean age was 53 years, 68 206 (44%) were men and 87 822 (56%) were women, and the mean baseline eGFR level was 86 mL/min/1.73 m². Patients just above and below the CTPA eligibility cutoff were similar in terms of measured confounders. There was no evidence for an association of contrast with eGFR up to 6 months later, with a mean change in eGFR of −0.4 mL/min/1.73 m² (95% CI, −4.9 to 4.0) associated with CTPA exposure. There was similarly no evidence for an association with need for kidney replacement therapy (risk difference [RD], 0.07%; 95% CI, −0.47% to 0.61%), mortality (RD, 0.3%; 95% CI, −2.9% to 3.2%), and acute kidney injury (RD, 4.3%; 95% CI, −2.7% to 12.9%), though the latter analysis was limited by missing data. Subgroup analyses were potentially consistent with harm among patients with diabetes (mean eGFR change −6.4 mL/min/1.73 m²; 95% CI, −15.4 to 0.2), but not among those with other reported risk factors for contrast-induced nephropathy; these analyses, however, were relatively underpowered.

CONCLUSIONS AND RELEVANCE Using a cohort study design and analysis that permits stronger causal interpretation than existing observational research, we found no evidence for a harmful effect on kidney function of intravenous contrast administered for CTPA in an emergency setting.
ne of the most important reported harms of radiocontrast administration is acute kidney injury (AKI), an adverse effect known as contrast-induced nephropathy (CIN). A number of recent observational studies, however, found no association between contrast exposure and adverse renal outcomes. These studies suggest that although CIN may have existed with contrast agents used in the past, modern agents and doses do not appear to be harmful. The existing evidence, however, is limited by a number of potential biases. First, confounding may result from baseline differences in the risk of developing kidney injury between exposure groups. For example, individuals receiving noncontrast CT scans, often used as a comparator group, may be receiving such a scan because they are perceived to be at high risk of kidney injury. In addition, selection bias may arise because many existing studies look at acute kidney injury (AKI) as their outcome, and limit study inclusion to those with appropriately timed repeat creatinine measurements. Although creatinine levels may be routinely measured after contrast exposure due to a belief in CIN, serial creatinine measurement in unexposed controls presumably reflects clinician beliefs that the patients have some other predisposition to AKI. These factors may contribute to forming a control group at high risk of kidney injury, creating a bias in favor of contrast and thus potentially masking harm. Despite several studies finding no evidence for CIN, their methodological limitations preclude clear causal interpretation and mean that concern over kidney injury from contrast exposure is still widespread among clinicians. As a result, important diagnostic imaging and procedures may be avoided due to fear of CIN, especially among patients with preexisting kidney impairment. To advance knowledge on this question, new analytical approaches that allow stronger causal interpretation are required.

### Methods

The present study seeks to overcome the limitations of existing research by using the regression discontinuity design (RDD). The RDD approach relies on the existence of a continuous variable, the running variable, for which there is a cutoff that determines eligibility for receiving treatment. Individuals who fall just either side of the cutoff have markedly different probabilities of receiving the treatment, but are expected to have very similar values of other characteristics, including potential confounders. By comparing outcomes in individuals just either side of the cutoff, the RDD approach can provide effect estimates from observational data that are largely free from both measured and unmeasured confounding. In the case of intravenous contrast, this will be achieved by studying individuals receiving D-dimer testing (the running variable) in the emergency department (ED). The most common indication for this test is suspected pulmonary embolism (PE), with those scoring above the cutoff—typically 500 ng/mL—more likely to receive contrast in the form of a computed tomographic pulmonary angiogram (CTPA) to rule in or rule out the diagnosis. Approval for this study was obtained from the Health Research Ethics Board of the University of Alberta (Pro00091579), including a waiver for obtaining participant consent due to the deidentified and retrospective nature of the data.

### Outcome and Exposure Variables

The primary exposure was long-term kidney function, measured by estimated glomerular filtration rate (eGFR) up to 6 months after the index ED visit. Long-term kidney function is a more patient-centered outcome than AKI because it is more proximate to harder clinical end points such as permanent kidney replacement therapy. It also helps address the problem of selection bias that arises with using AKI as an outcome, as the indications for testing eGFR months after the ED visit are much less likely to be affected by variables associated with the initial probability of CTPA exposure. Where multiple eGFR measurements were taken in the 6 months after the index visit, the latest measurement was used. Secondary outcomes were receipt of kidney replacement therapy (dialysis or kidney transplantation) in the 6 months after the index ED visit, AKI—defined as an increase in creatinine levels of 50% or 0.3 mg/dL (26 μmol/L) within 7 days—and all-cause mortality at 6 months.

The primary exposure was receipt of CTPA during the index ED visit. Additional covariates that may be associated with the outcome were included in the statistical analyses to improve the precision of effect estimates. These were age, baseline eGFR, sex, diabetes, hypertension, cancer, coronary

### Key Points

**Question** Is intravenous radiocontrast associated with clinically significant kidney injury?

**Findings** In this quasi-experimental cohort study of 156,028 individuals, exposure to intravenous contrast was associated with a 0.4 mL/min/1.73 m² reduction in estimated glomerular filtration rate up to 6 months later, which was not statistically significant nor clinically meaningful.

**Meaning** Intravenous contrast was not associated with significant long-term kidney injury; the regression discontinuity design used in this study allows for greater confidence that this effect estimate is not distorted by confounding.
artery disease, ED triage score, and Charlson comorbidity index. Further details on these variables are provided in Exposure Variables in the Supplement.

Statistical Analysis
We used a fuzzy RDD analysis to estimate the association of CTPA exposure with long-term eGFR, with D-dimer as the running variable. Fuzzy RDD is a form of instrumental variable analysis, where the magnitude of the jump or discontinuity in the exposure that occurs at the cutoff is used to rescale any discontinuity in the outcome that occurs at the cutoff.\(^5\) This maintains the unconfounded effect estimate of the RDD approach while accounting for imperfect compliance with the treatment cutoff. The resulting effect estimate is the complier average causal effect, which is the effect of the intervention among those whose treatment allocation is determined by the cutoff (compliers).\(^11\)

For each outcome, we report both the intention-to-treat (ITT) effect of crossing the D-dimer cutoff, and the rescaled complier average causal effect attributable to CTPA itself. For the primary outcome, the effect estimate will be the difference in long-term eGFR, whereas for the binary secondary outcomes, it will be the risk difference (RD). The associations between the running variable and both (1) the exposure and (2) the outcome were evaluated using local linear regression, with separate regression lines fitted above and below the cutoff.\(^26,27\) The difference in where these lines intersect the cutoff quantify the discontinuity in the exposure and outcome.\(^10\) The local linear approach minimizes bias by limiting the sample to a defined bandwidth around the cutoff in which a linear regression can be estimated. This reduces the risk of misspecification errors that may arise from the more complex functional forms that are needed to fit the regression curve across the whole range of the running variable values.\(^28\)

The size of the bandwidth, which was allowed to vary above vs below the cutoff, was automatically selected using a data-driven method that seeks to optimally balance the bias-variance trade off.\(^29,30\) We used an asymmetric bandwidth as we anticipated an asymmetric distribution of the running variable, D-dimer, and optimization of the bias-variance trade off may vary for the different regression slopes on either side of the cutoff. A triangular kernel was used, such that individuals closest to the cutoff were more heavily weighted than those further away. To account for potential misspecification of the regression function and the additional variance that this generates, bias-adjusted robust CIs were estimated.\(^31,32\)

Although in most hospitals in the study, a D-dimer cutoff of 500 ng/mL was considered a positive result, some used 460 ng/mL or 470 ng/mL as the cutoff.\(^33,34\) All participants therefore had their D-dimer centered on whichever cutoff was used in the institution of their index ED visit. Individuals whose D-dimer fell exactly on the cutoff were excluded from analysis because their classification with regard to the cutoff is ambiguous and may thus result in distortion of the treatment discontinuity.

Additional analyses were performed to assess the sensitivity of results to bandwidth size and symmetry, along with global (ie, whole data set) analyses using polynomials of varying degrees. Subgroup analyses were carried out to explore if the effect of treatment varied between groups considered to be at high and low risk of CIN.\(^35\) Finally, we performed an analysis using all eGFR measurements between 7 days and 6 months after the index ED visit as the outcome, with a variance estimator robust to clustering by participant,\(^37\) to determine if this could improve the precision of our effect estimates. Details of these additional analyses are provided in Supplementary Analyses in the Supplement.

All analyses were limited to complete cases. As a retrospective study relying on routinely collected clinical data, there may be significant missing data for the primary outcome of long-term eGFR and secondary outcome of AKI. We assessed whether this may give rise to selection bias by evaluating if (1) the frequency of missingness and (2) timing of data collection, changed at the cutoff. If there was no association between treatment group and data missingness, as evidenced by no change at the cutoff, this would provide confidence that the use of a complete case analysis would not result in marked selection bias. This reflects the fact that selection bias requires changes in the distribution of the exposure that occurs at the cutoff (eTable 3, eFigure 3 in the Supplement) for it to be significant missing data for the primary outcome of long-term eGFR.

This reflects the fact that selection bias requires changes in the distribution of the exposure that occurs at the cutoff (eTable 3, eFigure 3 in the Supplement) for it to be significant missing data for the primary outcome of long-term eGFR.

All analyses were performed using Stata statistical software (version 15, Stata Corp), with the primary and secondary analyses using the rdrobust package.\(^37\) Two-sided alpha was set at 0.05. The code used in the statistical analysis is available at https://github.com/goulden/contrast.

### Results
There were 156 028 individuals who received a D-dimer test and met inclusion criteria during the study period (eFigure 1 in the Supplement). Patient characteristics are described in Table 1. The mean age was 53 years, 68 206 (44%) were men and 87 822 (56%) were women, and the mean baseline eGFR was 86 mL/min/1.73 m\(^2\). eTable 1 in the Supplement provided group sample sizes.

Among those with D-dimer test results available at 7 days to 6 months following the ED visit was 3.7 months (interquartile range, 1.8-5.1). To account for potential misspecification of the regression function and the additional variance that this generates, bias-adjusted robust CIs were estimated.\(^31,32\)

Although in most hospitals in the study, a D-dimer cutoff of 500 ng/mL was considered a positive result, some used 460 ng/mL or 470 ng/mL as the cutoff.\(^33,34\) All participants therefore had their D-dimer centered on whichever cutoff was used in the institution of their index ED visit. Individuals whose D-dimer fell exactly on the cutoff were excluded from analysis because their classification with regard to the cutoff is ambiguous and may thus result in distortion of the treatment discontinuity.

Additional analyses were performed to assess the sensitivity of results to bandwidth size and symmetry, along with global (ie, whole data set) analyses using polynomials of varying degrees. All analyses were limited to complete cases. As a retrospective study relying on routinely collected clinical data, there may be significant missing data for the primary outcome of long-term eGFR and secondary outcome of AKI. We assessed whether this may give rise to selection bias by evaluating if (1) the frequency of missingness and (2) timing of data collection, changed at the cutoff. If there was no association between treatment group and data missingness, as evidenced by no change at the cutoff, this would provide confidence that the use of a complete case analysis would not result in marked selection bias. This reflects the fact that selection bias requires changes in the distribution of the exposure that occurs at the cutoff (eTable 3, eFigure 3 in the Supplement) for it to be significant missing data for the primary outcome of long-term eGFR.

All analyses were performed using Stata statistical software (version 15, Stata Corp), with the primary and secondary analyses using the rdrobust package.\(^37\) Two-sided alpha was set at 0.05. The code used in the statistical analysis is available at https://github.com/goulden/contrast.

### Data on the primary outcome, long-term eGFR, was available for 84 624 patients (54%) (eTable 2 in the Supplement). The frequency of missing eGFR measurements and their timing did not change at the cutoff (eTable 3, eFigure 3 in the Supplement). The median time to the last eGFR test in the 6 months following the ED visit was 3.7 months (interquartile range, 1.8-5.1). Bandwidths of 80 ng/mL below and 1190 ng/mL above the cutoff were automatically selected by the software
package, within which 29,830 patients were included. The estimated ITT effect of the D-dimer cutoff on long-term eGFR is depicted in Figure 2A, with a nonsignificant discontinuity of −0.1 mL/min/1.73 m² (95% CI, −1.2 to 1.1) (Table 2).

In the local linear fuzzy RDD analysis, there was no evidence of an association of intravenous contrast with long-term eGFR, with an eGFR change of −0.4 mL/min/1.73 m² (95% CI, −4.9 to 4.0) attributable to CTPA exposure caused by crossing the D-dimer cutoff (Table 2). A sensitivity analysis including all 84,624 patients and using a global cubic polynomial fuzzy RDD approach similarly found no evidence of an association, with an eGFR change of 0.4 mL/min/1.73 m² (95% CI, −2.1 to 2.8) attributable to CTPA exposure (Figure 2B; eTable 4 in the Supplement). Of 8 sensitivity analyses using different bandwidths and polynomial orders, 7 found no evidence of an association (eTable 4 in the Supplement).

Overall, 165 (0.11%) patients required kidney replacement therapy during the 6 months following their ED visit (161 dialysis, 4 kidney transplant). There was no evidence of an association of CTPA exposure with the need for kidney replacement therapy (RD, 0.07% [95% CI, −0.47% to 0.61%]) (Table 2; eFigure 4A in the Supplement). Of those with repeat creatinine levels measured within 7 days, 4147 (9.7%) developed AKI, with no evidence of an association of contrast exposure with this risk (RD, 4.3% [95% CI, −2.7% to 12.9%]) (Table 2; eFigure 4B in the Supplement). However, repeated creatinine measurements within 7 days were only available for 42,691 patients (27%), with a discontinuity in missingness at the cutoff (eTable 3, eFigure 5A in the Supplement). Overall, 6656 patients (4.3%) died in the 6 months following the index ED visit, with no evidence of an association with CTPA (RD, 0.3% [95% CI, −2.9% to 3.2%]).

Subgroup analyses (Table 3) found no evidence that the association of contrast with long-term eGFR varied by baseline eGFR, age, or hypertension. Among those with diabetes, the association was potentially consistent with harm although not statistically significant, with an eGFR change of −6.4 mL/min/1.73 m² (95% CI, −15.4 to 0.2; P for heterogeneity = .12). In a sensitivity analysis using all eGFR measurements 7 days to 6 months after the index ED visit as the outcome, CTPA exposure was associated with an eGFR change of −0.9 mL/min/1.73 m² (95% CI, −7.6 to 2.4).

### Discussion

In this large, multiyear study using population-based data, we found no evidence for an association of intravenous contrast with kidney function measured by eGFR up to 6 months after exposure to CTPA. There was similarly no evidence of an association with the risk of renal replacement therapy, all-cause mortality, or AKI, though the latter analysis was limited by missing data. Results were consistent across most subgroups thought to be at elevated risk of CIN, although these analyses were relatively underpowered.

Definitively proving a negative is difficult, but the results of our study suggest that a clinically significant association of intravenous contrast with long-term renal function is very unlikely. The lower 95% CI of our primary outcome, an eGFR drop of 4.9 mL/min/1.73 m², is less than one-fifth of a standard deviation of baseline eGFR and of limited clinical significance. Furthermore, the point estimates in our primary analysis and in 6 of the 8 sensitivity analyses (eTable 4 in the Supplement) yielded an eGFR difference (positive or negative) of less than 1.5 mL/min/1.73 m² attributable to CTPA. On the other hand, for our secondary outcomes of AKI and renal replacement therapy, it is more challenging to reject the possibility of an association. Although the difference was not statistically significant, the point estimate and upper 95% CI of the AKI outcome were consistent with a clinically significant association. However, this analysis may be at risk of selection bias (eTable 3 in the Supplement), and the null effect of the primary analysis suggests that if there was any acute kidney injury it did not progress to long-term injury. The point estimate and upper 95% CI of the kidney replacement therapy outcome were very small in absolute terms, though a clinically relevant relative effect could not be excluded.

In our subgroup analyses of potentially high-risk patients, none of the stratum-specific effect estimates or tests of heterogeneity led us to reject the null hypothesis of no effect. However, these analyses were relatively underpowered. The point estimates for most potentially high-risk subgroups—those with eGFR lower than 45 mL/min/1.73 m², older than 60 years, or hypertension—were very small, although their CIs included potentially clinically significant effects. The point estimate for patients with diabetes, however, was potentially compatible with clinically significant harm. Despite being an independent risk factor for acute and chronic kidney injury, most existing studies do not find evidence that diabetes specifically increases the risk of CIN. However, given the risk of residual confounding in existing research, and our finding

consistent with possible harm, further research using causally robust methodology is warranted in this subgroup.

These findings are consistent with a number of existing studies finding no association between intravenous contrast and kidney injury. However, our quasi-experimental design allows for causal interpretation with much greater confidence than existing research. At the D-dimer cutoff, there was no evidence of discontinuities in any of the measured confounders, analogous to a well-balanced randomized clinical trial, lending support to the idea that the same is true for unmeasured confounders.

An additional benefit of our study was the ability to evaluate the risk of selection bias. Unlike many other studies that limit inclusion to those with repeated creatinine measurements, our inclusion criteria were based solely on baseline characteristics. Although we performed complete case analyses, we were able to evaluate the risk of selection bias by exploring the association between the D-dimer cutoff and the risk of missing data (and hence exclusion from the analysis). The absence of a discontinuity in missingness means there is no association between exposure group and study inclusion, significantly reducing the possibility of selection bias. Of note, we did find evidence for an association between exposure status and outcome measurement for our secondary outcome of AKI, raising a concern for selection bias in studies that limit inclusion to those with repeat short-term creatinine measurements. Although there was no evidence of a discontinuity in missingness for our primary outcome, it remains possible that CTPA exposure would increase eGFR retesting for some (eg, by causing AKI) and decrease it for others (eg, by causing mortality), thus potentially giving rise to selection bias despite no detectable discontinuity in outcome missingness.

Additional strengths of our study include the large sample size, comprising more participants that the total number in a recent meta-analysis on this question, and the use of a comprehensive population-wide dataset, maximizing representativeness, and providing near complete outcome ascertainment for the kidney replacement therapy and mortality outcomes.

**Conclusions**

To our knowledge, this study provides the strongest evidence to date that intravenous contrast is not associated with significant kidney injury, further challenging the considerable clinical preoccupation with the occurrence and prevention of CIN.

**Limitations**

The principal limitation of any RDD analysis relates to the generalizability of the results. Because the treatment effect is estimated for those whose D-dimer value falls at the cutoff, it may not apply to those further away from this value. Because this is a fuzzy RDD analysis, the treatment effect is further restricted to those at the cutoff who are compliers ie, those whose receipt of a contrast-enhanced scan is determined by the cutoff. Individuals perceived to be at higher risk of kidney injury are less likely to have their CTPA receipt determined primarily by their D-dimer results, thus may be underrepresented among compliers. However, supplementary analyses found no evidence of heterogeneity of the treatment effect between compliers and noncompliers (Supplementary Analyses and eFigure 6 in the Supplement).

An additional potential limitation is violation of the exclusion restriction, whereby exposures other than intravenous contrast are affected by crossing the cutoff. It is likely that in patients perceived to be at high risk of kidney injury, clinicians would have taken steps to mitigate this risk, such as prescribing prophylactic prehydration. It was not possible to evaluate this directly because treatment data was not available in our data set. Whether such mitigation strategies would have masked any harm from contrast is called into question, however, by multiple randomized clinical trials showing no effect of these therapies on the risk of postcontrast AKI.

Randomized clinical trials (RCTs) are the gold standard of study design because randomization ensures that differences in outcomes between a treatment and control group reflect the causal effect of treatment. Although RCTs greatly benefit science and society for this reason, they often cannot be conducted because of logistical, ethical, or resource constraints.1 Researchers are thus confronted with many questions left unanswered.

To answer those questions, clinical investigators have traditionally turned to straightforward observational comparisons between treated and untreated (or differently treated) patients, relying on statistical techniques such as regression or propensity scores to control for confounders. Invariably, however, treated patients differ systematically from others in ways that are not measurable with the data collected. Researchers can control for observable differences, but unobserved differences remain to an unknown extent. The assumption necessary for causal conclusions from this type of observational research—no unmeasured confounding—is strong, if not heroic. Thus, the lingering question is whether the estimates are wrong, but how wrong.

A different approach to observational research is to search for sources of naturally occurring random assignment to treatment—RCTs conducted by circumstance as opposed to scientists. These unregistered trials abound, generating unreported results for researchers to harvest. The challenge is not to design them, but to find them.

This approach to causal inference from observational data, often called “quasi-experimental,” is standard in the social sciences. Like RCTs, this methodology addresses bias by design, minimizing the need to measure and control for confounders. Despite rapidly growing use of quasi-experimental methods in other fields, adoption in clinical research has been slow.1

In this issue of *JAMA Internal Medicine*, Goulden et al2 (a multidisciplinary team of clinicians and economists) use a regression discontinuity design to estimate the effect of intravenous (IV) contrast on kidney function. They exploit a D-dimer threshold commonly used to guide use of computed tomographic pulmonary angiography (CTPA). Because patients with D-dimer values just above vs below the threshold should differ minimally other than in their receipt of CTPA, the administration of IV contrast is effectively randomized among patients close to the threshold.

Overall, the authors find a large abrupt increase (discontinuity) at the D-dimer threshold in receipt of CTPA with IV contrast but no significant discontinuity in eGFR several months later, suggesting no evidence of contrast-induced nephropathy. Among high-risk patients with diabetes, however, they find a meaningful worsening in eGFR. These findings add considerably to our understanding of the safety of newer contrast agents, which has otherwise been based on hard-to-interpret results from observational comparisons subject to selection bias.

Because thresholds commonly determine clinical decisions, regression discontinuity analysis is a particularly promising tool for clinical research.3 Others have applied it to estimate the value of prostate-specific antigen screening, obesity counseling, and diagnosis of early-stage diabetes for patients just meeting a cutoff for further treatment.4 5 Goulden et al2 provide an imaginative and elegant application—one to learn from in the pursuit of evidence-based medicine with observational research methods.
