Andersen, MD; Krzysztof J. Misiukiewicz, MD; Christine H. Chung, MD; Jennifer E. Gerber, MSc; Shirani D. Rajan, MSPH; Gypsyamber D'Souza, PhD

IMPORTANCE Human papillomavirus–related oropharyngeal carcinoma (HPV-OPC) is increasing in incidence in the United States. Although HPV-OPC has favorable prognosis, 10% to 25% of HPV-OPCs recur. Detection of human papillomavirus (HPV) DNA in oral rinses is associated with HPV-OPC, but its potential as a prognostic biomarker is unclear.

OBJECTIVE To determine whether HPV DNA detection in oral rinses after treatment for HPV-OPC is associated with recurrence and survival.

DESIGN, SETTING, AND PARTICIPANTS Prospective cohort study of patients with incident HPV-OPC diagnosed from 2009 to 2013 at 4 academic tertiary referral cancer centers in the United States. Oral rinse samples were collected at diagnosis and after treatment (9, 12, 18, and 24 months after diagnosis), and evaluated for HPV DNA. Among an initial cohort of 157 participants with incident HPV-OPC treated with curative intent, 124 had 1 or more posttreatment oral rinses available and were included in this study.

MAIN OUTCOMES AND MEASURES Disease-free survival (DFS) and overall survival (OS) were estimated by the Kaplan-Meier method, and the association of HPV DNA detection in oral rinses with survival was evaluated using Cox regression analysis.

RESULTS Oral HPV type 16 (HPV16) DNA was common at diagnosis (67 of 124 participants [54%]). In contrast, oral HPV16 DNA was detected in only 6 participants after treatment (5%), including 5 with HPV16 DNA also detected at diagnosis (persistent oral HPV16 DNA). Two-year DFS and OS were 92% (95% CI, 94%-100%) and 98% (95% CI, 93%-99%). Persistent oral HPV16 DNA was associated with worse DFS (hazard ratio, 29.7 [95% CI, 9.0-98.2]) and OS (hazard ratio, 23.5 [95% CI, 4.7-116.9]). All 5 participants with persistent oral HPV16 DNA developed recurrent disease, 3 with local disease involvement. In contrast, just 9 of 119 participants (8%) without persistent oral HPV16 DNA developed recurrent disease, only 1 (11%) with local disease involvement. Median (range) time from earliest posttreatment oral HPV16 DNA detection to recurrence was 7.0 (3.7-10.9) months.

CONCLUSIONS AND RELEVANCE Human papillomavirus type 16 DNA in oral rinses is common at diagnosis but rare after treatment for HPV-OPC. Our data suggest that, although infrequent, persistent HPV16 DNA in posttreatment oral rinses is associated with poor prognosis and is a potential tool for long-term tumor surveillance, perhaps more so for local recurrence.
Human papillomavirus (HPV) infection is responsible for the majority of oropharyngeal carcinomas (OPCs) in the United States. Human papillomavirus–positive tumor status confers significantly improved prognosis; however, approximately 10% to 25% of patients experience disease progression after treatment, most within the first 2 years. Importantly, even after progression, HPV-related OPC (HPV-OPC) responds favorably to salvage treatment. Surgical salvage in particular is associated with improved outcomes for both HPV-positive and HPV-negative OPC, so surgically treatable HPV-positive disease is the most favorable scenario for patients with OPC progression. Currently, 35% to 45% of progressive HPV-OPCs have already spread to distant sites at the time of diagnosis, decreasing the feasibility of surgical salvage. Earlier diagnosis of progressive or recurrent disease than is currently possible, and especially of local or locoregional disease amenable to surgical treatment, would hasten initiation of salvage therapy and may improve outcomes.

To that end, the viral etiology of HPV-OPC, and the resultant association of HPV-specific biomarkers with HPV-OPC, presents an opportunity to potentially enhance posttreatment disease surveillance strategies and facilitate earlier diagnosis of progressive or recurrent disease. One such biomarker is human papillomavirus type 16 (HPV16) DNA in oral exfoliated cells, which is detected in up to two-thirds of HPV-OPC cases before treatment, and persists in a small subset of cases after treatment. Initial single-center studies suggest that HPV16 DNA detection in posttreatment oral rinses may also be associated with disease recurrence. Therefore, in this study we evaluated the prognostic and diagnostic implications of HPV16 DNA detection in serially collected posttreatment oral rinses within a prospective multicenter cohort of patients with HPV-OPC.

**Methods**

**Study Population**

The study population was a prospective multi-institutional cohort of participants with incident OPC diagnosed from 2009 through 2013 as previously described. Briefly, participants were enrolled at time of diagnosis, before treatment initiation (“diagnosis”). Oral rinse samples were prospectively collected with behavioral and clinical data. Computer-assisted self-interview surveys were administered at diagnosis and then at 12 and 24 months after diagnosis to collect behavioral and demographic data, including self-designated race because HPV-OPC incidence and behavioral risk factors vary by race. Medical record abstraction was performed annually, with abstraction last updated in October 2014 for all participants. Tumor HPV status was determined by in situ hybridization for HPV DNA and immunohistochemical analysis for p16, as previously described. Clinical care, including treatment regimen and posttreatment disease surveillance, was carried out consistent with established national guidelines at the 4 participating academic head and neck oncology centers.

Participants eligible for this analysis had HPV-OPC treated with curative intent, clinical follow-up for at least 12 months after diagnosis, and at least 1 posttreatment oral rinse. This study was approved by the institutional review board at all study sites, and all participants gave written informed consent.

**HPV Detection in Oral Rinses**

Oral rinse and gargle samples were collected using 10 mL of Scope mouthwash at diagnosis and again after treatment, at 9, 12, 18, and 24 months after diagnosis. Oral rinse samples were tested for 36 types of HPV DNA using PGMY09/11 primers and line-blot hybridization as described previously. Types of HPV considered high-risk were types 16, 18, 31, 33, 35, 39, 45, 51, 56, 58, 59, 68, and 73. Persistent oral HPV DNA detection was defined as detection of the same high-risk HPV (HR-HPV) type at diagnosis and in at least 1 posttreatment oral rinse.

**Analytic Methods**

Frequency and percent, or median and interquartile range (IQR), of participant characteristics were described overall and by eligibility for this analysis. Viral load was reported as both a categorical and a continuous variable by characteristics of interest. Categorical variables were compared using χ² or Fisher exact tests, and continuous variables, using the Wilcoxon nonparametric rank-sum test.
Survival rates were estimated using the Kaplan-Meier method. Overall survival (OS) was defined as time from diagnosis to death from any cause, with censoring at last follow-up. Disease-free survival (DFS) was defined as time from diagnosis to disease recurrence, with censoring at last follow-up or death. Survival curves were compared using the log-rank test. Risk factors for mortality and recurrence were explored using Cox regression models.

Specificity, sensitivity, positive predictive value (PPV), and negative predictive value (NPV) of HPV16 DNA detection in posttreatment rinses as a predictor of recurrence (considered as binary) were also explored. Oral rinse results at the 9- and 12-month visits and the 18- and 24-month visits were combined for some analyses. There were no discordant oral HPV16 DNA detection results at these pairs of visits. P < .05 was considered statistically significant. Data analysis was performed using STATA 11.2.

Results

Study Population

Of the 157 participants with HPV-OPC, 124 (79%) had at least 1 posttreatment oral rinse sample and were therefore eligible for this analysis. The characteristics of the study population are summarized in Table 1. The majority of participants were male (90%), white (98%), married or living as married (85%), and never-smokers (58%). Most participants had small tumors (65%) and advanced nodal (70%) and overall stage (82%). Compared with ineligible participants, eligible participants were more likely to be married (P = .03), had higher income (P = .009), and had fewer pack-years of smoking (P = .02) (eTable 1 in the Supplement).

HPV Detection in Oral Rinses at Diagnosis and After Treatment

Detection of HPV16 DNA in oral rinses was common in participants at diagnosis (67 of 124 [54%]) (Table 2). A median (range) of 3 (1-4) posttreatment oral rinses was available per participant. Nearly all (113 [91%]) participants had an oral rinse at 9 to 12 months after diagnosis, and 89 (72%) had an oral rinse at 18 to 24 months. Detection of HPV16 DNA in oral rinses was rare after treatment. Only 6 of 124 participants (5%) had detectable HPV16 DNA in any posttreatment oral rinse, including 4 prevalence (4 of 113) at 9 to 12 months and 3% (3 of 89) at 18 to 24 months after diagnosis. Most oral HPV16 DNA detected at diagnosis cleared after treatment (62 of 67 participants [93%]).

Detailed characteristics of the 6 participants with HPV16 DNA detected in any posttreatment oral rinse are displayed in Table 3. The most common pattern observed among these 6 participants was persistent detection of oral HPV16 DNA at diagnosis and in all posttreatment rinses (4 participants [patients 1-4]) (timeline shown in eFigure 1 in the Supplement). In contrast, 1 participant (patient 5) had oral HPV16 DNA detected at diagnosis that cleared temporarily but was again detected at 18 and 24 months. Finally, there was 1 participant (patient 6) in whom oral HPV16 DNA was not detected at diagnosis, then was newly detected at 12 months, and subsequently cleared.

Oral rinses were also evaluated for DNA from 12 other HR-HPV types besides HPV16 (called HR-HPV hereafter) (Table 2). High-risk-HPV DNA was less common than HPV16 DNA in oral rinses at diagnosis, observed in 27 (22%) compared with 67 (54%) of participants (P < .001). Most type-specific HR-HPV infections present at diagnosis cleared after treatment (21 of 28 [75%] infections corresponding to 20 of 27 [74%] participants), whereas 7 (25%) infections persisted (corresponding to 7 [26%] participants) (Table 2). Interestingly, there were also 14 new type-specific HR-HPV infections detected after treatment in 12 participants. Thus, the majority of times that non-HPV16 HR-HPV DNA was detected after treatment appeared to represent newly detectable, as opposed to persistent, HR-HPV infections (14 of 21 type-specific infections [67%]). Participants with vs without newly detected type-specific HR-HPV infections did not significantly differ with regard to sexual behaviors, smoking status, or other characteristics (eTable 2 in the Supplement).

Recurrence and Survival

Median (IQR) follow-up time was 33 (24-41) months. There were 14 recurrences and 6 deaths observed during follow-up among the 124 participants. All 6 deaths were from recurrent disease. Two years after diagnosis, disease-free survival (DFS) was 92% (95% CI, 94%-100%) and overall survival (OS) was 98% (95% CI, 93%-99%).

Detection of HPV16 DNA in oral rinses at diagnosis was not associated with DFS (P = .15) or OS (P = .14). In contrast, persistent HPV16 DNA detection in oral rinses (eg, both at diagnosis and any time after treatment) was associated with a greater than 20-fold increased risk of recurrence (hazard ratio [HR], 29.7 [95% CI, 9.0-98.2]) and death (HR, 23.5 [95% CI, 4.7-116.9]) in univariate analysis (Table 1, Figure). After adjustment for pack-years of smoking and tumor stage, persistent detection of oral HPV16 DNA remained associated with both DFS (adjusted HR [aHR], 35.8 [95% CI, 8.6-149.1]) and OS (aHR, 16.1 [95% CI, 2.8-92.7]). Number of pack-years of cigarette smoking was also associated with worse DFS (HR, 1.4 [95% CI, 1.1-1.8] per 10 pack-years) and OS (HR, 1.5 [95% CI, 1.2-2.1]) in univariate analysis, consistent with previous research, although these associations were no longer significant after adjustment for persistent oral HPV16 DNA and tumor stage (aHR for DFS, 1.2 [95% CI, 1.0-1.5] and aHR for OS, 1.3 [95% CI, 0.9-1.8]). Sex, alcohol use, tumor subsite, age, and study site were not significantly associated with DFS or OS.

All 5 participants with persistent oral HPV16 DNA detected developed recurrent disease and 3 died of disease, whereas the 1 participant with newly detected oral HPV16 DNA after treatment that subsequently cleared (patient 6) was alive without disease at last follow-up, 23 months after diagnosis (Table 3, eFigure 1 in the Supplement). The median (range) time from first posttreatment detection of oral HPV16 DNA to recurrence was 7.0 (3.7-10.9) months for the 4 participants with study visits prior to recurrence (patient 2 did not have any posttreatment study visits until after recurrence).

Four of the 5 participants with persistent oral HPV16 were originally treated with chemoradiation therapy and the fifth
with surgery and adjuvant radiation therapy, which did not differ from the overall study population (P = .65, Fisher exact test) or from the 9 participants who experienced disease recurrence but did not have persistent oral HPV16 DNA (P = .30).

Three of the recurrences among the 5 participants with persistent oral HPV16 DNA included local disease (Table 4). In comparison, nearly all recurrences among participants without persistent oral HPV16 DNA were regional and/or dis-

Abbreviation: HPV16, human papillomavirus type 16.

a HR-HPV not including HPV16.
b Any HR-HPV, including HPV16.
c Defined as detection of HR-HPV DNA in oral rinse at diagnosis but not in any posttreatment oral rinse.
d Participants with an oral rinse from either the 18-month and/or the 24-month (after diagnosis) study visit were included (n = 89): 45 had both 18- and 24-month oral rinses (all concordant), 17 had only 18-month and 27 had only 24-month oral rinses.

Although without local disease (8 of 9 [89%]; P = .10, Fisher exact test) (Table 4), overall, only 3 participants developed isolated local or locoregional recurrence without distant disease; 2 of these had persistent oral HPV16 DNA (patients 3 and 4) and 1 did not.

We estimated the ability of persistent HPV16 DNA in oral rinses to predict future recurrence by considering only oral rinses collected within 9 to 12 months after diagnosis and evaluating recurrence risk only within 12 to 24 months after diagnosis, eg, recurrences within approximately 1 year subsequent to the oral rinse sampling. There were 3 participants with persistent oral HPV16 DNA detected at 9 to 12 months, of whom all 3 experienced disease recurrence between 12 and 24 months after diagnosis. In contrast, there were 108 participants without persistent oral HPV16 DNA at 9 to 12 months, of whom 4 (4%) experienced recurrence. Therefore, although there were few events, detection of HPV16 DNA in oral rinses at 9 to 12 months after diagnosis in our study population had high specificity (100% [95% CI, 96%-100%]), PPV (100% [95% CI, 29%-100%]), and NPV (96% [95% CI, 91%-99%]), but low sensitiv-
ity (43% [95% CI, 12%-80%]), in predicting any subsequent recurrence within the following year. Interestingly, all 3 recurrences predicted by the presence of persistent oral HPV16 DNA involved local disease (1 local, 1 locoregional, and 1 locoregional and distant), compared with none of the 4 recurrences in participants without persistent oral HPV16 DNA (2 regional and distant, 2 distant only; \( P = .03 \), Fisher exact test). When only recurrences involving local disease were considered in this analysis, specificity and PPV remained at 100% (95% CI, 97%-100% and 29%-100%, respectively), whereas sensitivity increased to 100% (95% CI, 29%-100%), as did NPV (100% [95% CI, 97%-100%]).

In contrast to the observed association of persistent oral HPV16 DNA detection with survival, persistent detection of DNA from HR-HPV types other than HPV16 was not associated with survival (\( P = .40 \) and .65 for DFS and OS, respectively). Among the 7 participants with persistently detected HR-HPV other than HPV16 (including HPV 33, 39, 45, 51, and 52 and 2 participants with HPV59), there was only 1 recurrence, in a participant with persistent oral HPV52 DNA who developed pulmonary metastases.

HPV16 Viral Load in Oral Rinses at Diagnosis
There were 57 participants with detectable HPV16 viral load in oral rinses at diagnosis, 56 (98%) of whom also had HPV16 DNA detected by line-blot hybridization (eTable 3 in the Supplement). Median (IQR) detectable HPV16 viral load in oral rinses at diagnosis was 161 (21-846) copies/2 μL. Participants with larger tumors more commonly had a detectable oral HPV16 viral load than those with smaller tumors (62% vs 43%; \( P = .05 \)), and current smokers were more likely than never or former smokers to have high (>160 copies/2 μL) viral load (46% vs 21%; \( P = .04 \)). High viral load was also more common in participants with tonsil compared with nontonsil tumors (39% vs 11%; \( P < .001 \)).

Higher HPV16 viral load in oral rinses at diagnosis was associated with significantly worse OS (\( P \) for trend = .01) but was not significantly associated with worse DFS (\( P \) for...

Discussion

Although most HPV-OPCs respond favorably to treatment, a subset of patients experience disease progression. There is a need for clinically relevant biomarkers of disease recurrence to facilitate timely initiation of aggressive diagnostic investigation and subsequent salvage treatment to potentially improve outcomes for the growing population of HPV-OPC survivors. Detection of recurrent local or locoregional disease prior to distant spread is particularly desirable given the favorable response of HPV-OPC to surgical salvage. We have demonstrated that persistent HPV16 DNA detection in posttreatment oral rinses, although infrequent, is predictive of HPV-OPC recurrence, perhaps even more so for local recurrence, and is associated with survival. Furthermore, we observed a clinically meaningful lead time from first positive posttreatment oral rinse result to diagnosis of recurrence (median, 7 months). Therefore, HPV16 DNA detection in oral rinses may provide a valuable tool for long-term posttreatment surveillance of HPV-OPC for local recurrence.

Our study corroborates in a multicenter, prospective cohort setting the findings of 2 previous smaller cohort studies that described an association of HPV16 DNA detection in posttreatment oral rinses with survival. Chuang et al detected HPV16 DNA in oral rinses from 2 of 20 patients with HPV-OPC or HPV-positive unknown primary tumors from 1999 through 2005, both of whose disease recurred 3.5 months after the oral rinse sample was collected. Ahn et al reported that of 83 patients with OPC and unknown primary tumors from 1999 to 2010 (72 HPV positive), 4 had HPV16 DNA detected in posttreatment oral rinses, and 3 subsequently had recurrent cancers (aHR for recurrence-free survival, 10.7 [95% CI, 2.4-48.5]). The higher HR that we report (aHR, 35.8 [95% CI, 8.6-149.1]) is likely explained by our restriction to patients with HPV-OPC and use of persistent, rather than any, posttreatment oral HPV16 DNA for our analysis. Risk estimates may also be influenced by different laboratory methods for HPV detection in each study. Of note, 1 additional study by Koslabova et al did not observe prognostic significance of posttreatment oral HPV16 DNA detection. Reasons for this discrepancy are unclear but may relate to their use of a single post-treatment oral rinse, heterogeneous patient population, and/or limited clinical follow-up.

The consistent finding that HPV16 DNA detection in posttreatment oral rinses is predictive of recurrence in our and several previous studies supports its potential utility as a clinical test. Our study has several strengths. First, the multisite, prospective cohort design and recent calendar period (2009-2013) lend generalizability and current relevance to our findings. We included only participants with HPV-OPC, decreasing heterogeneity. Finally, the serial collection of posttreatment oral rinse samples at predefined intervals allowed us to preliminarily describe a time lag from first HPV16 DNA-positive oral rinse to recurrence.

These findings highlight the question of what HPV16 DNA detected in posttreatment rinses represents pathophysiologically. We hypothesize that the persistent presence of oral HPV16 DNA represents in most cases integrated or episomal viral DNA in persistent or recurrent microscopic disease that may not yet be detectable by conventional methods. Of note, our laboratory methods cannot distinguish between HPV DNA in infectious viral particles and integrated or episomal HPV DNA in tumor cells (for this reason, we have largely referred to “oral HPV DNA detection” rather than “oral HPV infection”). However, it has been shown that most HPV16 strains detected in oral rinses of patients with HPV-OPC are genetically identical to the HPV16 found in corresponding tumors. Further, we previously reported that partners of patients with HPV-OPC do not exhibit a higher than expected prevalence of HPV16 DNA detection in oral rinses. Taken together, this is more consistent with noninfectious fragments of HPV16 DNA in exfoliated tumor cells, rather than an active infection, as the primary source of the HPV16 DNA detected in oral rinses from patients with HPV-OPC.

Although based on few events, our analysis of the predictive value of persistent oral HPV16 DNA at 9 to 12 months after diagnosis demonstrated high specificity, sensitivity, PPV, and NPV for subsequent recurrence involving local disease in the following year. This is clinically significant, in that isolated local or locoregional tumor is more amenable to salvage treatment, especially surgical salvage. Although only 2 of the 5 participants with persistent oral HPV16 DNA had such isolated local or locoregional recurrence, it is conceivable that earlier and more aggressive diagnostic workup for the remaining 3 participants, precipitated by an HPV16-positive oral rinse, may have facilitated detection of disease at a more limited, and therefore treatable, stage.
The low sensitivity of our assay for any recurrence, including regional and distant disease, is not surprising because regional or distant metastatic disease would not, in the absence of a direct connection to the primary site, be expected to shed tumor cells into an oral rinse. A potential strategy to increase sensitivity for recurrence overall is to combine oral rinses with plasma-based testing for HPV16 biomarkers, such as HPV16 DNA or antibodies to HPV16 antigens, which has also been shown to be sensitive for HPV-OPC and is less anatomically constrained.11,14,22

The prognostic value of persistent oral HR-HPV DNA detection in posttreatment oral rinses was limited in our study to HPV16, whereas persistence of other HR-HPV types was not associated with recurrence or survival. Because HPV16 is responsible for more than 90% of HPV-OPCs,23,24 DNA from other HR-HPV types is less likely to be etiologically related to tumor recurrence. In addition, the demographic characteristics of our study population are such that a relatively high baseline prevalence of oral HR-HPV DNA detection is expected: the prevalence of oral HR-HPV infection in the general population is 3.7% but is greater among men in their mid-50s with high numbers of lifetime oral sex partners,25 all characteristics typical of patients with HPV-OPC. This may also explain the high rate of newly detected non-HPV16 HR-HPV DNA after treatment, which was also noted in previous studies.12,14

Our finding that HPV16 viral load in oral rinses at diagnosis was associated with worse survival has not to our knowledge been previously reported, and the clinical relevance is unclear because there were few events in our study. It is possible that higher viral copy number may correlate to some measure of disease activity, for example, tumor size, and portend increased resistance to treatment. Additional studies are necessary to replicate and further characterize this association. The higher viral load among smokers is consistent with previously reported data from the general population,26 and the association of detectable viral load with tumor size is not surprising because larger tumors would be expected to shed more tumor cells; however, the significantly increased viral load in participants with tonsillar compared with other oropharyngeal tumors was unexpected. This may reflect a differential capacity of an oral rinse to sample tumor tissue depending on primary site of disease.

The conclusions of this study are limited by the infrequency of persistent oral HPV16 DNA detection and small number of deaths and recurrences. In addition, the lack of posttreatment disease surveillance standardized restricted analysis of the timing of oral rinse results relative to clinical and imaging findings. Finally, eligible participants were significantly more likely than ineligible participants to have several characteristics associated with improved prognosis after head and neck cancer treatment, in that they were more likely to be married, had higher income, and had fewer pack-years of smoking, which may have biased our results.

Conclusions
Detection of HPV16 DNA in oral rinse samples is common at diagnosis but rare after treatment for HPV-OPC. Our data suggest that persistent HPV16 DNA detection in posttreatment oral rinses, although uncommon, is associated with poor prognosis and may be predictive of disease recurrence, in particular local recurrence. Therefore, HPV16 DNA detection in oral rinses is a potentially useful tool for long-term tumor surveillance for the growing population of HPV-OPC survivors.
Human Papillomavirus 16 DNA in Oral Rinses for Oropharyngeal Carcinoma

Original Investigation Research

Persistent Salivary Human Papillomavirus DNA as a Surveillance Biomarker
Not Just Spitting in the Wind

Julie E. Bauman, MD, MPH; Robert L. Ferris, MD, PhD

Although patients with human papillomavirus (HPV)-associated oropharyngeal squamous cell carcinoma (OPSCC) have a much better prognosis than HPV-negative patients, up to 25% still experience recurrence. Furthermore, efforts to reduce toxic therapy are controversial due to the potential risk for increasing recurrence; thus, early detection of residual or recurrent disease is important to institute salvage therapy.

In this issue of *JAMA Oncology*, Rettig and colleagues1 show that persistent oral HPV type 16 (HPV16) DNA, measured in pre- and posttreatment rinses of patients undergoing curative-intent therapy for HPV-positive OPSCC, is a harbinger of poor recurrence-free survival. Whereas their data are intriguing, an important clinical question is raised: Does the oral rinse, a non-invasive surveillance tool, identify subclinical local or locoregional recurrence (LRR) at a time amenable to surgical salvage?
